## Clinical and Experimental

The Biologic Decay Periods of Sodium in Normal Man in Patients With Congestive Heart Failure and in Patients With the Nephrotic Syndrome as Determined by Na as the Tracer Sam Threefoot M D George Burch M D and Paul Reaser M D., New Orleans La	1
Theoretic Considerations of Biologic Decay Rates of Isotopes George E Burch M D Sam A Threefoot M D and James A Cronvich M S New Orleans La	14
The Nature of the Altered Renal Function in Lower Nephron Nephrosis Daniel Marshall M D and William S Hoffman M D Ph D Chicago Ill	31
Histopathology of the Liver in Human Brucellosis Wesley W Spink M D Frederick W Hoffbauer M D., Walter W Walker M D and Robert A Green M D Minneapolis Minn	40
The Treatment of Pneumococcal Pneumonia by Penicillin in Aqueous Solution at Long Intervals Morton Hamburger M D Jerome R Berman M D Robert T Thompson M D and M A Blankenhorn M D Cincinnati Ohio	59
New Penicillin Products for Sustained Effects Leo Loewe M D Albert E Sobel Ph D and Erna Altire Werber Ph D Brooklyn N Y	67
The Turbidimetric Assay of Hyaluronidase Sibylle Tolsdorf Ph D Mar an H McCready B A D Roy McCullagh Ph D and Erwin Schwenk D Sc Bloomfield N J	74
Sickle Cell Disease Studied by Measuring the Survival of Transfused Red Blood Cells Sheila T E Callender M D James F Nickel M D and Carl V Moore M D, Department of Internal Medicine Washington University and Barnes Hospital St Louis Mo and E O Powell Oxford England	90

(Contents continued on inside front cover)

## Contents—(Continued from front cover)

Use of Thymol Turbidity as Lipid Absorption Test    Hans Popper, M D, Ph D, Frederick Steigmann, M S, M D, Hattie Dyniewicz, Ph C, and Alvin Dubin, M S, Chicago, Ill -----	105
The Bound Glucosamine of Serum Mucoid in Diabetes Mellitus, Fluctuations Observed Under the Influence of Insulin    Henry R Jacobs, M D, Evanston, Ill -----	116
Dibutoline as an Antidote for Diisopropyl Fluorophosphate Poisoning in Mice Cloice H Biggins, M D, Loma Linda, Calif -----	123
Pharmacology of Allylthiomethyl- and <i>n</i> -Butylthiomethylpenicillin    C L Rose, A B, P N Harris, M D, O K Behrens, Ph D, and K K Chen, M D, Ph D, Indianapolis, Ind -----	126

### Laboratory Methods

A Method for the Determination of Fibrin Appearance Time    Arthur B Voorhees, Jr M D, Samuel Graff, Ph D, and Arthur H Blakemore, M D, New York, N Y -----	133
A Simple Mixing and Shaking Apparatus    Thomas F Frawley, M D, and Charles W Bishop, Ph D Buffalo, N Y -----	140
An Electronic Apparatus for Recording Blood Pressure    David F Marsh, Ph D, Morgantown, W Va -----	143
An Optically Recording Bubble Flow Meter Adapted for Measurement of Renal Blood Flow    Ewald E Selkurt, Ph D, Cleveland, Ohio -----	146

## Clinical and Experimental

Studies With Colloids Containing Radioisotopes of Yttrium Zirconium Columbium and Lanthanum I The Chemical Principles and Methods Involved in Preparation of Colloids of Yttrium Zirconium Columbium, and Lanthanum John W Gofman MD PhD Berkeley Calif	297
Studies With Colloids Containing Radioisotopes of Yttrium Zirconium Columbium and Lanthanum II The Controlled Selective Localization of Radioisotopes of Yttrium, Zirconium and Columbium in the Bone Marrow Liver and Spleen Ernest L Dobson MA John W Gofman MD PhD Hardin B Jones PhD Lola S Kelly BA and Leonard A Walker BS Berkeley Calif	305
An Experimental Study of the Effect of Zirconium and Sodium Citrate Treatment on the Metabolism of Plutonium and Radioyttrium Jack Schubert PhD Chicago Ill	313
The Significance of the Amino Acid Composition of the Proteins Excreted by the Nephrotic Child Anthony A Albanese PhD Virginia I Davis BS Emilie M Smetak and Marilyn Lein New York N Y	326
Nutritional Status and Infection Response II Electrophoretic Circulating Plasma Protein Hematologic Hematopoietic and Pathologic Responses to Mycobacterium Tuberculosis (H37RV) Infection in the Protein Deficient Rat Jack Metcalf MS MD Dorothy Darling MS Doris Wilson BSc Angelo Lapi MD and F J Stare MD PhD Boston Mass	335
Resistance of the Tubercle Bacillus to Streptomycin Benjamin Blattberg MA and Helen Ehrhorn BS Staten Island N Y	358
Blood and Cerebrospinal Fluid Concentrations of Aureomycin After Oral and Intramuscular Administration Mark H Lepper MD, Harry F Dowling MD Robert L Brickhouse MD and Eston R Caldwell Jr MD Washington D C	366
The Action of Thephorin Upon Histamine Induced Gastric Secretion in Dogs and on Gastric Ulcer Formation in Rats G Lehmann MD and Paul L Stefko Nutley N J	372

(Contents continued on inside front cover)

## Contents—(Continued from front cover)

The Effects of Intravenously Administered Histamine on the Peripheral Circulation in Man Khalil G Wakim, M D, Ph D, Gustavus A Peters, M D, Jean C Terrier, M D, and Bayard T Horton, M D, Rochester, Minn .....	380
Photoelectric Determination of Arterial Oxygen Saturation in Man Earl H Wood, M D, Ph D, and J E Geraci, M D, Rochester, Minn With the Technical Assistance of M Neher and L Cronin .....	387
Isolation of Herpes Simplex Virus on the Chorioallantoic Membrane Lewis L Coriell, M D, Harvey Blank, M D, and T F McNair Scott, M D, Philadelphia, Pa With the Technical Assistance of Lillian T Schermerhorn .....	402
The Therapeutic Effect of Tryptophane in Human Pellagra Richard W Vilter, M D, John F Mueller, M D, and William B Bean, M D, Cincinnati, Ohio ..	409
A Study of Histochemical Iron Using Tracer Methods K M Endicott, M D, T Gillman, M D, G Brecher, M D, A T Ness, Ph D, F A Clarke, B S, and E R Adamik, Bethesda, Md .....	414
<b>Laboratory Methods</b>	
Needle Biopsy of the Liver Using Oxidized Cellulose and Thrombin to Prevent Hemorrhage H L Clay, M D, and Lewis Dickinson, M D, Louisville, Ky .....	422
Detection of Bromate in Blood and Urine A L Dunn, Ph D, and A R McIntyre, M D, Ph D, Omaha, Neb .....	425
The Use of Azoalbumin as a Substrate in the Colorimetric Determination of Peptic and Tryptic Activity Rudolph M Tomarelli, Ph D, Jesse Charney, M S, and Mary Lord Harding, M N, Philadelphia, Pa .....	428
A Hematologic Slide Rule for Calculating the Corpuscular Constants William R Best, M D, Chicago, Ill .....	434
Note on a Substance to Seal Plethysmographic Cups of the Burch-Winsor Type C W Robertson, M D, and R H Smithwick, M D, Boston, Mass .....	438

# THE BIOLOGIC HALF LIFE PERIODS OF SODIUM IN NORMAL MAN IN PATIENTS WITH CONGESTIVE HEART FAILURE, AND IN PATIENTS WITH THE NEPHROTIC SYNDROME AS DETERMINED BY $Na^{22}$ AS THE TRACER

SAM THRELOOT M.D. GEORGE BURCH M.D. AND PAUL RIASI M.D.  
NEW ORLEANS, LA.

A substance introduced into an organism tends to be eliminated exponentially; that is the amount excreted is a fairly constant percentage of that which remains. Mathematically the substance is never completely eliminated, and it is therefore preferable to measure the interval of time required to eliminate one half the material introduced; this is known as the *biologic half life period* of the substance. It is important to know this measurement for several reasons:

(1) The length of time required to excrete one half an isotope or labeled substance introduced into an organism is equal to the time required to excrete one half the total amount of the regular form of the substance already present in the organism. Therefore a measurement of the biologic half life period of the substance introduced indicates the total rate of turnover of the regular substance.

(2) Whenever radioelements are introduced into an organism the *safety factor* is determined in part by the time interval of exposure of the organism to radiations from the radioelement. Radioelements with a long physical half life such as  $Na^{22}$  or  $C^{14}$ , will not decay rapidly enough to change their activity appreciably. The degree of their action upon the organism on the other hand is reduced as the radioelement is excreted. Therefore from a knowledge of the biologic half life period the duration of exposure of the organism to the radiations of the substance is known.

(3) *Safety measures* of public health importance are concerned with the biologic half life period of radioelements and these problems will assume greater import as radioelements are more widely employed.

(4) The biologic half life period of a substance influences the *nature of the study* concerned with labeling by radioactive substances, such as the rate of collection of samples of biologic fluids, the time at which animals must be sacrificed, and clinical management of human subjects. For example, a radioelement with a relatively long biologic half life period and a very short physical half life is not suitable for tracer studies involving over all turnover in the organism.

From the Department of Medicine Tulane University School of Medicine and Charity Hospital of Louisiana.

Aided by grants from the Life Insurance Medical Research Fund a War Contract No. WD 49 007 MD 389, Hells Institute for Medical Research and the Mrs. E. J. Calre Fund for Research in Heart Disease.

Presented at the second annual meeting of the Southern Society for Clinical Research New Orleans, La. Jan. - 1948.

Received for publication July 9 1948.

(5) The biologic half-life period is an important factor in calculating dosages of radioelements to insure levels of counts which permit accuracy of measurements

(6) The influence of *disease* upon the biologic half-life is significant from the point of view of understanding disease and of planning further investigations

(7) This measurement is also valuable in clarifying problems related to *therapy*, characteristics of species in animals and plants, toxicology, and many other problems peculiar to individual experiments

The wide variations in metabolic activity, diet, and general biologic processes affect the biologic half-life of radioelements considerably. This is true in health and particularly in disease. For this reason, values for the biologic half-life of a substance for a normal organism cannot be applied empirically to an abnormal one. For example, since the excretion of a substance varies with each subject and with the intake of that substance by the organism, any interpretation based upon an average biologic half-life period is only an approximation for some other subject with a different intake and a different biologic state.

During the course of the study of the rate of sodium turnover in normal human subjects and the influence of congestive heart failure on sodium excretion with a limited supply of long half-life radiosodium ( $\text{Na}^{22}$  with  $t_{1/2}$  of three years), sufficient data were obtained to indicate the biologic half-life period of sodium in man. These help elucidate the influences of diet and drugs upon the biologic half-life in normal man as well as in patients with chronic congestive heart failure and in those with the nephrotic syndrome of chronic glomerulonephritis.

#### MATERIALS AND METHODS

In the studies with  $\text{Na}^{22}$  not designed primarily for measuring the biologic half-life period of sodium, twelve subjects were observed continuously for periods varying from twenty to seventy days. Four of these were normal subjects, six had chronic congestive heart failure (two were slowly improving, two rapidly improving, and two slowly becoming worse), and two patients had the nephrotic syndrome of chronic glomerulonephritis (see Table I for clinical details).

$\text{Na}^{22}$ , as  $\text{NaCl}$  in approximately 2 cc of water, was administered intravenously to each subject. Doses with an activity such that there were 17,725,000 counts per minute (about 09 mc) were administered to seven subjects (Nos. 2, 3, 4, 5, 6, 11, and 12), 12,500,000 counts per minute (about 06 mc) to three subjects (Nos. 1, 7, and 9), and 10,000,000 counts per minute (about 05 mc) to two subjects (Nos. 8 and 10). It was found that sufficiently high counts could be obtained by injection of smaller doses, necessitated by the limited supply of  $\text{Na}^{22}$ .

Each specimen of urine during the entire period of study was collected separately, and daily blood samples were taken. The volume of each urine specimen, and the radioactive count, were recorded so that total elimination of radiosodium could be determined. Counts of blood serum were followed as an index of radiosodium concentration in the extracellular fluid.

Sixteen free falling drops of urine or serum from a calibrated micropipette were placed on filter paper disks fixed with rubber cement to metal disks so that the quantity and geometric characteristics of each sample remained constant. The samples were counted for

five minutes with mica window Geiger Muller counters. Corrections for background were made, and the data were recorded in counts per minute per cubic centimeter of fluid. In order to compare the concentrations of radiosodium in the serum, all counts were corrected to correspond to an injected dose of 17,750,000 counts per minute for each subject. The range of error was plus minus 3 per cent.

The urinary excretion of Na was expressed in terms of the percentage of injected Na which was not eliminated by the kidneys. This value, represented symbolically as %N<sub>t</sub>, was calculated from the equation

$$\%N_t = \left( 1 - \frac{\sum k}{N} \right) \times 100$$

where

N = injected Na in counts per minute

k = Na excreted in urine only during the s<sup>th</sup> day after injection expressed in counts per minute

%N<sub>t</sub> = percentage of injected Na not excreted in urine by the end of the t<sup>th</sup> day after injection

Weights and fluid intake and output were recorded daily for each subject. The sodium intake was varied in some instances from low (<17 Gm NaCl per day) to regular (8 Gm NaCl per day), to high (13.7 Gm NaCl per day), and the effect on the rate of elimination of radiosodium was noted. Mercurial diuretics\* and other drugs, used frequently in both the diseased and normal subjects, exerted some influence on the rate of excretion of the radio sodium.

Fig 1—Semilogarithmic graphs of relation of changes in serum  $\text{Na}^{22}$  concentration (counts per minute per cubic centimeter) to time

A, Four subjects without cardiovascular disease. The mean rate of fall in concentration was such that half-concentration was reached in 13.3 days ( $C_{1/2}$ ).

B, Normal Subject No 1, showing a change in rate of fall in concentration with variations in sodium content of the diet low sodium diet (17 Gm NaCl daily) and high sodium diet (137 Gm NaCl daily). At rate a, with low sodium diet serum concentration reached half the initial value in twenty-five days. At rate b with a high sodium diet half serum concentration was reached in eight days and at rate c when a low sodium diet was resumed half-concentration was reached in eighteen days.

## RESULTS

Results are summarized in Table II and in Figs. 1, 2, 3, 4, and 5.

*1 Controls*—In the four control subjects who had no disturbance in the cardiovascular system and no edema, the serum concentration of  $\text{Na}^+$  dropped to half the initial level in an average of 13.3 days, the extremes being twelve and fourteen days (Table II and Figs. 1 and 4). The rate of elimination of the isotope in the urine was such that one half of the  $\text{Na}^+$  administered would have been excreted in an average of 28.8 days, with a range of nine and forty-two days (Table II and Figs. 3 and 4). Subject No. 1 demonstrated the influence which intake of sodium chloride has on the rate of elimination of  $\text{Na}^+$  from the body (Figs. 1, B and 3, B). The rate of decline in serum concentration whereby one half the initial concentration was reached in twenty-five days when the patient was given 1.7 Gm. of available sodium chloride increased to a rate whereby one half the initial concentration was attained in eight days (three times as rapid) when 13.7 Gm. of available chloride was allowed and then changed again to a reduced rate of eighteen days when the patient again received 1.7 Gm. available sodium chloride (Fig. 1, B). Similar response was noted for rates of elimination in the urine (Fig. 3, B).

*2 Patients With Chronic Congestive Heart Failure*—

*(a) Patients Slowly Improving*—In two patients who were slowly recovering from congestive heart failure forty and forty-two days were required for the serum concentration of  $\text{Na}^+$  to reach one half the initial level (Table II and Figs. 2, A and 4). These patients required about three times as many days as the control subjects for reduction of serum concentration of  $\text{Na}^+$  to half the initial level. The  $\text{Na}^+$  was excreted in the urine at such a rate that sixty and seventy-two days would have been required to excrete one half the administered  $\text{Na}^+$  (Table II and Figs. 3, C and 4). The rate of excretion of  $\text{Na}^+$  in the urine of the control subjects was more than twice as rapid as in the patients with heart failure.

*(b) Patients Rapidly Improving*—The two patients with chronic congestive heart failure who improved rapidly required an average of 20.5 days (extremes, thirteen and twenty-eight days) for the serum concentration of  $\text{Na}^{22}$  to reach one half the initial level (Table II and Figs. 2, B and 4). The mean rate of excretion of  $\text{Na}^{22}$  was 29.5 days, the extremes being twenty-six and thirty-three days (Table II and Figs. 3, D and 4). Although the average rate of decline in the serum concentration in Patient No. 7 was thirteen days, once improvement began, the rate of decline exceeded that of the control subjects. Initially the rate of decrease in blood concentration of  $\text{Na}^+$  was such that half concentration would have been reached in fifty-five days. During rapid improvement, however, this level was attained in six days, a rate more rapid even than that of the control subject on a high sodium intake. The rates of elimination of  $\text{Na}^+$  in the urine of this patient tended to parallel changes in concentration in the serum (Figs. 2, B and 3, D). Patient No. 8 also showed two rates of decline in serum concentration of  $\text{Na}^{22}$  (seventy-one and twenty-four days respectively required to reach

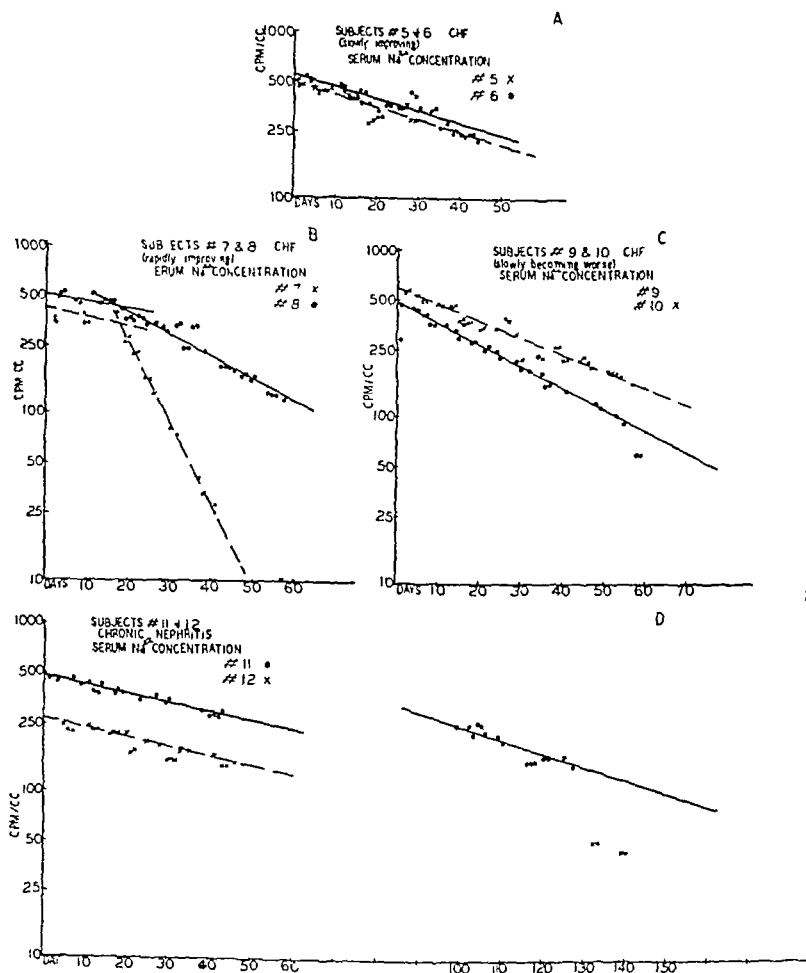

Fig 2—Semilogarithmic graphs of changes in serum  $\text{Na}^{22}$  concentration (counts per minute per cubic centimeter) as a function of the time for six patients with congestive heart failure and two patients with the nephrotic syndrome of chronic glomerulonephritis

*A, Two patients with congestive heart failure who were slowly improving* Patient No 5 showed a mean rate of fall in serum  $\text{Na}^{22}$  concentration so that half-concentration was reached in forty days ( $C_{1/2}$ ). Patient No 6 showed a mean rate of fall in concentration so that half-concentration was reached in forty-two days. It may be noted on the graphs that for each of these patients several rates of change existed, although only the mean rate is shown by the straight line.

*B Two patients with congestive heart failure who were rapidly improving* Patient No 7 showed two distinct rates of fall in serum  $\text{Na}^{22}$  concentration. The first rate, maintained for eighteen days, was such that half-concentration would have been reached in six days. Patient No 8 also showed two distinct rates of fall in serum  $\text{Na}^{22}$  concentrations. The first rate present for eighteen days was such that half-concentration would have been reached in seventy-one days whereas with the second rate twenty-four days would have been necessary.

*C, Two patients with congestive heart failure who were slowly becoming worse* Patient No 9 showed a mean rate of fall in serum  $\text{Na}^{22}$  concentration so that half-concentration was reached in twenty-four days ( $C_{1/2}$ ). Patient No 10 showed a mean rate of fall in concentration so that half-concentration was reached in thirty days. Several rates of change in concentration may be noted although only the mean rate for each patient is indicated by the straight line.

*D, Two patients with the nephrotic syndrome of chronic glomerulonephritis* Both of these patients were discharged from the hospital and later readmitted for continuation of the studies. On the first admission Patient No 11 showed a mean rate of fall in serum  $\text{Na}^{22}$  concentration so that half-concentration would have been reached in fifty-eight days ( $C_{1/2}$ ). During the second period of study this patient showed a mean rate of fall in concentration so that half-concentration would have been reached in thirty-seven days and Patient No 12 required fifty-four days.

half concentration) and at least two rates of elimination of Na in the urine (Figs 2, B and 3, D) These two patients eliminated Na more rapidly than the two patients who were improving slowly

(c) *Patients Slowly Becoming Worse* Two patients gradually became clinically worse throughout the period of study The serum concentration of Na was reduced to one half the initial value in an average of twenty seven days the extremes being twenty four and thirty days (Table II and Figs 2 C and 4) The mean rate of loss of Na in the urine was such that one half the administered Na would have been excreted in sixty days, with extremes being forty eight and seventy two days (Table II and Fig 3, F) These patients required a longer period of time to excrete the Na than did the control subjects or the patients with congestive heart failure who were rapidly improving but essentially the same time was necessary in patients who were slowly improving

3 *Patients With the Nephrotic Syndrome of Chronic Glomerulonephritis* — The two patients with the nephrotic syndrome showed the slowest rates of elimination of Na The decline in the serum concentration of Na was such that an average of fifty six days (extremes fifty four and fifty eight) would have been required for the serum level to reach one half the initial value (Table II and Figs 2, D and 4) The rate of Na excretion in the urine was extremely slow in both patients an average of 513 days would have been necessary to eliminate one half the Na administered (Table II and Fig 3, F) The control subjects exhibited a rate of decline in the serum concentration of Na<sup>22</sup> more than four times as rapid as in these patients and the rate of urinary elimination was ten to twenty times as rapid (Table II and Fig 4)

#### DISCUSSION

Morgan<sup>1</sup> suggested the symbol "Te" for the body elimination half life This term is satisfactory if the time required to eliminate one half the radioactive material administered can be determined without too much difficulty Unfortunately, this is not easily accomplished in man, especially for sodium Results indicate that there are considerable variations in normal as well as in diseased man Because of these wide variations from moment to moment and because of differing conditions of environment, diet physical activity, severity stage and course of disease, therapy, previous physiologic state and many other factors, it is possible to obtain only an approximation of the time required to eliminate one half the radioactive material administered Furthermore values observed for changes in blood concentration differ from those for elimination in the urine (Table II Figs 1 to 4) It is, therefore, preferable to indicate in the symbol for the half elimination time the method by which the value was obtained It is suggested that the following symbols be employed in the discussion of rates of elimination

$B_{1/2}$  = *biologic half life*, that is the time required to eliminate one half the administered tracer substance from the body This corresponds to the "Te" value of Morgan

$C_{1/2}$  = *concentration one half*, that is the length of time required for the concentration of the tracer material in the body fluid or substance or

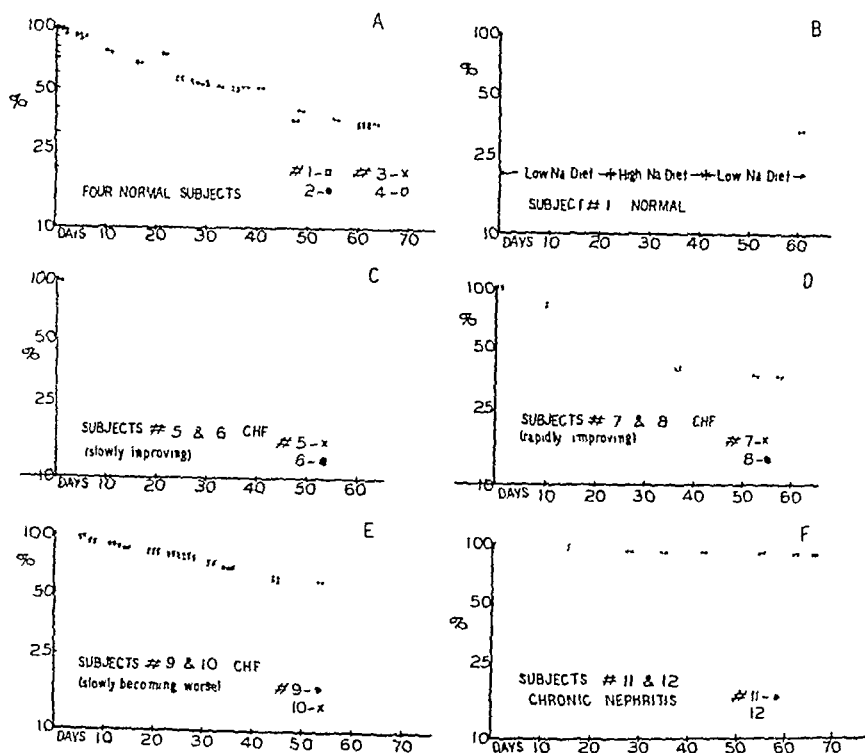

URINARY EXCRETION OF  $\text{Na}^{22}$ 

Fig 3—Semilogarithmic graphs for all subjects showing the urinary excretion of  $\text{Na}^{22}$  (percentage of injected  $\text{Na}^{22}$  which was not eliminated by the urine). This value was obtained from the total counts of  $\text{Na}^{22}$  excreted daily through the urine. That for the first day was subtracted from the total counts injected the total for each successive day was subtracted serially. Each resultant was then expressed as a percentage of the total injected dose. These values represent that radiosodium which has remained within the body plus that which has been excreted by some other route i.e. that  $\text{Na}^{22}$  which has not been eliminated in the urine. This also indicates the rate of excretion by way of the urine.

A. Four subjects without cardiovascular disease. If all the  $\text{Na}^{22}$  were eliminated in the urine the day upon which one-half of the injected radiosodium would have been excreted (mean value  $U_{1/2}$ ).

B. Normal Subject No. 1 shows changes in rate of excretion of  $\text{Na}^{22}$  in the urine with changes in the sodium content of the diet. For twenty-two days during a low sodium diet the rate of elimination in the urine was such that one-half the sodium present in the body would have been eliminated in one hundred days ( $U_{1/2}$ ). For the next nineteen days during a high sodium diet the rate of excretion increased so that one-half the body sodium would have been excreted in the urine in nineteen days. For the last nineteen days of observation during a low sodium diet and administration of antidiuretics the rate of urinary excretion of body sodium was such that 250 days would have been required for excretion of one-half the sodium present at the beginning of that period. Actually one-half the injected  $\text{Na}^{22}$  was excreted in thirty days.

C. Two patients with congestive heart failure who were slowly improving. Several different rates of excretion for each patient may be noted the mean rate for the two patients being sixty-six days for excretion of half the  $\text{Na}^{22}$  injected.

D. Two patients with congestive heart failure who were rapidly improving. Several rates of excretion may be observed. The mean length of time required to excrete one-half the injected  $\text{Na}^{22}$  by the urine was 29.5 days ( $U_{1/2}$ ).

E. Two patients with congestive heart failure who were slowly becoming worse. Changes in rate of excretion may be noted as in the other subjects. The mean time necessary for excretion of one-half the injected sodium through the urine was sixty days.

F. Two patients with the nephrotic syndrome of chronic glomerulonephritis. If sodium were excreted only by the urine a mean of 513 days would have been required to excrete one-half the injected radiosodium.

specific compartment to reach one half the concentration existing at any time after equilibrium of distribution of the tracer has been reached. It is thus possible to speak of the  $C_1$  for cerebrospinal fluid,  $C_2$  for hepatic parenchyma,  $C_3$  for blood serum.

$U_{1/2}$  = *primary elimination one half* that is the length of time necessary to eliminate in the urine one half the tracer material administered.

From the point of view of *safety*<sup>1</sup> it is actually the  $C_1$  that is important. Since the  $C_{1/2}$  and  $U_{1/2}$  are sometimes extremely different, particularly in abnormal states (Table II, Lines 2, 3 and 4), the  $U_{1/2}$  value is of little assistance in calculation of dosages and may result in error.  $B_1$  is certainly important but is not easily determined in man especially for sodium. Such a determination would require measuring all of the radiosodium excreted by *all* avenues for long periods in a great many persons under varying conditions of diet, environment, disease, and therapy; this is a tremendous task. With the present state of knowledge of radioelements and biologic influences of radioactivity,  $C_{1/2}$  and  $U_{1/2}$  furnish important data of useful physiologic nature. The possibilities of variations in  $B_1$ ,  $C_1$ , and  $U_{1/2}$  are discussed in a second paper, and various mechanisms by which they may differ considerably are suggested.

In all subjects studied  $C_{1/2}$  was less than  $U_{1/2}$  except in Control Subject No. 2. Careful analysis of the data failed to suggest a rational explanation for this discrepancy.  $U_{1/2}$  is expected to be greater than  $C_{1/2}$  since sodium is eliminated by avenues other than the urine such as sweat, tears, sputum, feces, vomitus, and other body fluids. "Binding" of sodium in cells and onto cells, proteins, and other complex molecules can account in part for these differences. These factors should be studied in experiments designed to determine the  $B_1$ ; the present experiments, however, were planned for other purposes and it was not possible to make these measurements. They were satisfactory for determining the  $C_{1/2}$  and  $U_{1/2}$  in the subjects observed.

The  $C_1$  and  $B_{1/2}$  would be expected to be identical in subjects in whom the size of the sodium compartment fails to change, and this is more likely to occur in normal than in diseased subjects. This is probably true for Control Subject No. 1, who was apparently normal in every respect. This was true clinically for Subject No. 2 except that she had fever with arthralgia three weeks before initiation of the studies. Control Subjects Nos. 3 and 4, who suffered from dyspepsia from time to time and experienced vomiting occasionally, were not truly normal but could be considered so for practical purposes.

It is obvious from the values obtained for  $C_{1/2}$  and  $U_{1/2}$  that  $Na^{24}$  is not suitable for measuring these parameters or for measuring  $B_{1/2}$ . Na on the other hand, is excellent for such purposes. Although the supply of Na was limited, a relatively large number of subjects was observed for long periods of time. If the  $C_{1/2}$  values approximate the  $B_{1/2}$ , the physical half life period (three years) of Na is of little value in safety considerations for the subject, because the radiosodium is excreted long before sufficient physical decay can occur, that is for biologic purposes,  $Na^{24}$  may be considered stable.  $Na^{24}$ , on the other hand, rapidly decays to levels of radioactivity too low for accurate measurements of biologic decay periods.

Fig 4—A bar diagram of the mean  $C_{1/2}$  (value of time days) for the serum  $Na^{22}$  concentration to reach one-half the initial equilibrium concentration ( $C_{1/2}$ ) and the mean time for one-half the injected  $Na^{22}$  to be excreted in the urine ( $U_{1/2}$ ). The mean value for each group is enclosed in the column and the extremes are indicated above the column

Although the subjects were followed for as many as sixty consecutive days, the  $C_{1/2}$  or  $U_{1/2}$  values often exceeded this period considerably, so that it was necessary to extrapolate the observed curves to obtain the values of  $C_{1/2}$  and  $U_{1/2}$  recorded. This was true for only two of the  $C_{1/2}$  determinations and for seven of the  $U_{1/2}$ . Therefore, all the values of  $C_{1/2}$  and  $U_{1/2}$  actually indicated the rates of change that existed only for the days observed.

A number of factors other than excretion can alter the  $C_{1/2}$ . As mentioned previously, a fixation of sodium to cells or protein and other large molecules will reduce the sodium content of the serum and the  $Na^{22}$  concentration. Fixa-

tion of binding of the tracer can result in a state such that  $C_{1/2}$  cannot be equal to  $B_{1/2}$ . Another important factor is a discrepancy in water intake and output particularly in states of edema. When more water is taken in than is excreted

# RELATION OF DIET TO CHANGES IN RATES OF EXCRETION AND OF DECREASE IN SERUM CONCENTRATION OF $Na^{22}$

SUBJECT NO

FIG 5—The relationship of change in sodium content of the diet and change in the rate of decrease of serum  $Na^{22}$  concentration and change in the rate of urinary excretion of  $Na^{22}$  for each subject. Sodium content of the diet is indicated by HS (high sodium 13.7 Gm NaCl daily) LS (low sodium less than 1 Gm NaCl daily) PS (regular sodium intake 8 Gm daily). Changes in rates are denoted by arrow. ↑ indicates a more rapid rate of change in serum  $Na^{22}$  concentration or rate of urinary excretion. ↓ indicates a reduction in either rate. Time is recorded as days of observation. High correlation of change in diet and change in rate may be noted in Subject No 1 but poor correlation exists in the others (see text).

then the  $Na^{22}$  content of the body fluids will be diluted and the serum  $Na^{22}$  concentration will be diminished. If  $Na^{22}$  counts for the serum had been employed alone in the interpretations the rate of excretion of  $Na^{22}$  so obtained would have been inaccurate. In fact, if the sodium excretion fell almost to zero in a man who rapidly became edematous shortly after administration of a tracer dose of  $Na^{22}$  and if the edema were sufficiently severe to double the volume of the sodium compartment of the body then the  $Na^{22}$  concentration in the serum would be reduced to one half the initial value. Thus the subject might attain a  $C_{1/2}$  value without excreting any sodium but such a value would certainly differ greatly from the  $B_{1/2}$ . This dilution phenomenon was noted in some of the edematous patients studied (Subjects No 9, 11 and 12).

If the reverse situation occurs that is if an intensely edematous subject loses water more rapidly than sodium, then an actual rise in the serum concentration of  $Na^{22}$  and therefore in the  $C_{1/2}$  time would ensue. Here too the

$C_{1/2}$  and  $B_{1/2}$  values would differ. It is obvious then, that the  $C_{1/2}$  and  $B_{1/2}$  values cannot be accepted as similar, particularly in subjects with edematous states.

A glance at the biologic decay curves reveals considerable fluctuation in the serum concentration of  $\text{Na}^{22}$ . These fluctuations are partially due to technical variations but in greater part are attributable to changes produced by phenomena described in the preceding paragraph. Furthermore, some of the variations are the result of responses to drugs and other pharmacologic reactions. The responses to such materials as desoxycorticosterone acetate, mercurial diuretic, sodium chloride and water intake, betahypophamine, and ammonium chloride were studied. These substances definitely influenced the  $C_{1/2}$ ,  $U_{1/2}$  and  $B_{1/2}$  of the subjects. In some instances these correlations were difficult to interpret whereas in others they were easy. For example, in Subject No. 1, the  $C_{1/2}$  and  $U_{1/2}$  were influenced significantly by the sodium intake in the diet, a correlation made possible by allowing mainly dietary sodium to vary (Figs 1 B and 3 B). When the subject was on a low sodium chloride diet (17 Gm of available NaCl),  $C_{1/2}$  and  $U_{1/2}$  were definitely longer than during the interval when he was receiving relatively large quantities of sodium (137 Gm of available NaCl). For example, initially while on a low sodium intake,  $C_{1/2}$  and  $U_{1/2}$  values were twenty-five and one hundred days respectively, on high sodium intake they were reduced to eight and nineteen days, and when a low sodium intake was resumed, the  $C_{1/2}$  and  $U_{1/2}$  values lengthened to eighteen and two hundred and fifty days respectively. The correlations were impressive and, of course, predictable. Most subjects, however, failed to show a definite relationship between  $C_{1/2}$  and  $U_{1/2}$  and sodium intake (Fig 5). This failure is related to other factors such as drugs, water intake, and the like, which influence  $C_{1/2}$  and  $U_{1/2}$ .

Another obvious factor of importance to consider when measuring the  $C_{1/2}$  and  $B_{1/2}$  in edematous subjects is that concerned with the mechanical removal of fluids from various compartments of the body. For example, if large quantities of ascitic fluid or pleural fluid are removed from a subject at equilibrium and containing  $\text{Na}^{22}$ ,  $B_{1/2}$  will be changed without changing  $C_{1/2}$ . This factor may become significant in a subject who is receiving repeated paracenteses. Proper considerations can be made for such factors.

Extremely edematous subjects who rapidly improve may excrete sodium at a rate considerably greater than that observed in the normal subject under the same therapeutic regimen. This phenomenon was noted for Subject No. 7, who had severe chronic congestive heart failure with anasarca. Diuresis was intense and prolonged, and during this period the  $C_{1/2}$  and  $U_{1/2}$  were six and twenty-two days respectively. The  $C_{1/2}$  was shorter than that observed for the control subjects, even when sodium intake was high. Obviously, the subject was excreting the fluid of edema and  $\text{Na}^{22}$  at a rapid rate, with the  $\text{Na}^{22}$  elimination out of proportion to the water. This resulted in a relatively short  $C_{1/2}$ . At the same time the  $B_{1/2}$  period would have to be short.

The results demonstrate reduction of sodium excretion in patients with chronic congestive heart failure and chronic glomerulonephritis of the nephrotic type. The mean  $C_{1/2}$  periods were several times longer for these diseased sub-

jects than for the controls. There were periods of improvement however for patients with congestive heart failure when  $C_{1/2}$  and  $U_{1/2}$  were shortened. These observations indicate the importance of considering the abnormal state in calculation of safety doses of radiosodium. It is essential that such variations of  $B_{1/2}$  be known for any type of radioelement.

It is relatively easy to determine  $C_{1/2}$  and  $U_{1/2}$  for a radioelement whereas for a labeled compound or even a simple molecule it is much more difficult. The labeling isotope is being 'turned over' in the molecule of the labeled substance, and the substance itself is always in the process of breakdown and partial or complete resynthesis. Sometimes it is even possible to label complex structures to trace them. But  $B_{1/2}$  a parameter difficult to evaluate even for elements. This is well exemplified by the measurement of the  $B_{1/2}$  period of erythrocytes with  $\text{Na}^{24}\text{I}$  is not as satisfactory as  $\text{Na}^{24}$  and  $\text{P}^{32}$  is even less satisfactory as a tracer isotope because it does not remain within the erythrocytes throughout their life. Proper consideration must be given such problems in determination of the  $C_{1/2}$ ,  $U_{1/2}$ , or  $B_{1/2}$  periods.

#### SUMMARY

Rates of elimination of sodium were studied with  $\text{Na}^{24}$  as a tracer in normal man and in man suffering from chronic congestive heart failure or from chronic glomerulonephritis of the nephrotic type.

Because of the nature of the experiments the true biologic half life period ( $B_{1/2}$ ) was not measured directly. Instead the time necessary to reduce the serum concentration to one half the initial level after the establishment of equilibrium ( $C_{1/2}$ ) and the time required to eliminate one half the injected Na in the urine ( $U_{1/2}$ ) were determined.  $t_{1/2}$  values obtained were usually less than the  $U_{1/2}$  ones.  $C_{1/2}$  in the control subjects most probably was equal to  $B_{1/2}$  but this was not likely to be true for the abnormal subjects.  $C_{1/2}$  and  $U_{1/2}$  varied considerably with normal physiologic phenomena and with such abnormal states as congestive heart failure, nephrosis, and with administration of drugs, and sodium and water intake. For example a diet low in salt appeared to lengthen the time of  $C_{1/2}$  and  $U_{1/2}$  whereas a diet high in salt was shown to shorten them.

$C_{1/2}$  was increased about threefold in patients with chronic congestive heart failure and about fivefold in the presence of the nephrotic syndrome.  $U_{1/2}$  was increased to an even greater extent by these diseases and was influenced by the progress of the process. When the diseases were aggravated and fluid of edema was accumulating the influence of dilution modified the  $C_{1/2}$ .

The importance of these observations and the relative general significance of  $B_{1/2}$ ,  $C_{1/2}$ , and  $U_{1/2}$  periods in the biologic application of radioelements, particularly radiosodium, have been discussed.

# THEORETIC CONSIDERATIONS OF BIOLOGIC DECAY RATES OF ISOTOPES

GEORGE E BURCH, M D , SAM A THREEFOOT, M D , AND  
JAMES A CRONVICH, M S \*  
NEW ORLEANS, LA

THE rate with which isotopes are eliminated from an organism is of importance physiologically, in safety considerations, in calculation of dosages, and for many other reasons. In previous studies<sup>†</sup> concerned with biologic decay periods for the radioactive isotope of sodium ( $\text{Na}^{22}$ ), it became necessary to enter into theoretic considerations of rates of change in concentration of the isotope in the body fluids and in other compartments as well as rates of elimination. These considerations hold for any tracer and for the entire organism or any compartment within it, regardless of size or location. Results obtained and concepts developed are worthy of report because of their general application to biologic and other tracer experiments.

After a single administration of an isotope and establishment of homeostasis, elimination and change in concentration of the isotope in the compartments of the body are dependent upon many related factors. Only a few of the factors are relatively fixed, and variations in them may increase with abnormal states. The patterns of elimination and variations in concentration are complex. For example the excretion of an isotope is related to such phenomena as the following:

- 1 There is daily lowering in concentration and/or total amount of the isotope within the body because of continuous excretion. From experimental work done to date, it appears that excretion occurs exponentially.

- 2 Change in concentration of the tracer material results whenever the volume of the isotopic compartment varies.

- 3 The daily intake of the nontracer form of the element usually affects the behavior of the tracer form.

It is impossible to consider all the factors associated with elimination of an isotope or variations in concentrations within its compartments in the body, among those herein considered are:

- 1 Variations in intake of the nontracer form of the substance.

- 2 Variations in rates of elimination of the nontracer substance from the organism.

- 3 Variations in volume of the compartments of the substance.

†Threefoot, S. A., Burch, G. E., and Reaser, P. "The Biologic Decay Periods of Sodium in Normal Man, in Patients With Congestive Heart Failure and in Patients With the Nephrotic Syndrome as Determined by  $\text{Na}^{22}$  as the Tracer." *J. Lab. & Clin. Med.* 34: 1, 1949.

These factors deserve attention in biologic work concerned with tracer studies, since any one of them can produce a considerable change in concentration or elimination of the tracer element. For this reason such phenomena which are independent of the physiologic processes being observed must be evaluated adequately or controlled.

It is well to define certain terms employed in this discussion.

*Elimination* denotes any movement of the substance being studied from the compartment under observation. For example, if the sodium in the extracellular fluids passes into cells or into the urine it is considered to have been eliminated from the compartment of extracellular fluid regardless of the mechanism by which this transfer occurs.

*Intake* refers to any addition of the substance to the compartment under study. Thus, sodium added to the extracellular fluid compartment from the diet or from mobilization of sodium from bones or cells is considered intake.

*Volume of the compartment* indicates the volume of that portion of the organism which is under study with the tracer. It is much safer to include in any compartment that portion of the organism which is physiologically (including physical and chemical behavior) homogeneous. For example, it would be less satisfactory to group all portions of the body in which sodium is found as the sodium compartment than it would be to consider separately the sodium compartment of extracellular fluid, of bone, of cerebrospinal fluid, and so forth. This is particularly true when rapid or sudden changes are occurring in the element being traced.

From the three terms just defined it becomes obvious that it is possible to consider the whole organism as one compartment or any portion of it as a compartment, for example, the extracellular fluid space, pleural cavity, individual cell, or nucleus of a cell.

#### THE PROBLEM

It is advisable at this moment to present briefly the problem to be considered in these discussions. This can be done satisfactorily through the medium of Fig. 1, which illustrates a tank. At time  $t$  this tank contains a compartment with a volume,  $V_i$ , into which is dispersed a substance  $M_i$  in solution or other state, to be observed. To the tank there is being added continuously more of the material which constitutes the dispersing compartment or medium  $V_i$  as well as more of the substance to be observed,  $I$ . Simultaneously, a certain amount of the dispersing medium  $V_k$  and a certain amount of the substance under observation  $K$ , are being removed continuously from the tank through a stopcock. If it is desired to trace this substance within the tank, then at a time  $t = 0$  the known quantity of a tracer form,  $N$ , should be added to the tank. If it is added at a given moment, it soon attains equilibrium of distribution with the nontracer form the substance to be observed. Moreover, it is important to remember that since the tracer form is *not* added continuously, this form  $N$  is being removed *gradually* from the tank by way of the stopcock.

Fig 1—Diagram of a tank or compartment containing  $\text{Na}^{23}$  in water in which the concentration of  $\text{Na}^{23}$  remains constant.  $\text{Na}^{23}$  as a tracer substance is added at an instant to label the  $\text{Na}^{23}$ . The  $\text{Na}^{23}$  and  $\text{Na}^{23}$  are always thoroughly mixed. To this tank more  $\text{Na}^{23}$  and water are being added while  $\text{Na}^{23}$ ,  $\text{Na}^{23}$  and water are constantly being removed. The problem is to determine the change in total quantity and concentration of the  $\text{Na}^{23}$  (the tracer substance) within the tank for various rates of intake and output of  $\text{Na}^{23}$  (the nontracer substance). Man or any organism or portion of an organism may be compared to the tank see text for details

#### CONSIDERATIONS

1 If **CN**, concentration of the tracer element, is being observed in order to gain qualitative and quantitative information concerning the tracer substance, **N**, and the nontracer substance, **M**, then it is necessary to realize that

(a) **CN** is being affected by the escape of **N** from the tank if **V**, the volume of the compartment, does not change proportionately

(b) **CN** changes if **N<sub>K</sub>** (the excretion of **N**) is zero, but **V** changes

(c) **CN** is dependent upon the relative variations in **N<sub>K</sub>** and **V**. **V**, of course, depends upon the relative variation in **V<sub>I</sub>** and **V<sub>K</sub>**

2 The total quantity of **N**, independent of concentration within the tank at any given time varies with the rate of discharge of **N** from the tank

3 The tank may be considered to be any living organism, such as man, in which a substance is being studied by the tracer technique. Under biologic conditions certain further restrictions would have to be imposed upon the "tank". For example if an electrolyte, whose role in the problem of isotonicity is important, is being traced, a proportionate increase in the volume of water will be necessary whenever the electrolyte accumulates within the tank. This is true to a minor degree when such substances as fat or glycogen are under observation. Therefore if **V**, the volume of the dispersing compartment, varies then the concentration of **N** will vary accordingly. Furthermore, if a

restriction is applied to the tank so that the osmotic force of  $M$  within  $V$  is constant, then the variations in concentration of  $N$  and  $M$  and in the quantity of  $N$ ,  $M$ , and  $V$  will be determined by the relative intake and elimination of  $M$  and  $V$ . *Changes in the concentration and total quantity of  $N$  within the tank will be determined by the relative intake and output of  $M$  and  $V$ .*

*Analogy Between the Tank and Man*—Any living organism as a whole or any part of the organism regardless of size may be compared to the tank. With such analogies however certain factors must be taken into account for example state of equilibrium homogeneity of the compartment and substances under study disturbances in functions concerned with the problem as well as physiologic, physical and chemical peculiarities inherent in the substance being traced and in the compartment in which it resides. These and other matters will reveal themselves as the discussions progress.

In order to simplify the considerations suppose that man is the tank and sodium is the substance  $M$ , under study. Then the sodium compartment  $V$  will consist of all portions of the body throughout which sodium is distributed. The principal sites are extracellular fluids and bone and to a lesser extent cells and proteins. Since the greatest portion of the sodium  $M$ , is found within the extracellular fluids of the body and since the extracellular fluids must remain isotonic to be compatible with life then in man the quantitative relationship of  $M$  and  $V$  is so restricted that accumulation of one within the body is necessarily accompanied by a proportionate accumulation of the other. If a tracer form of sodium  $N$  ( $Na^{22}$ ) is suddenly added to the body of man to trace the ordinary sodium  $M$  then as in the tank absolute and relative variations in  $L$ , the intake of nontracer sodium ( $Na$ ) in  $V_i$  the intake of water, in  $K$ , the output of nontracer sodium ( $Na$ ) and in  $V_o$  the output of water will influence  $CN$  and the total quantity of  $N$  within the body at any time as well as  $N_i$ . If such factors as the rate of intake alone of ordinary sodium ( $Na$ ) will influence the rate of change in concentration or total amount of the tracer sodium ( $Na$ ) then such factors must be evaluated when a substance within the body is being traced since it is necessary to distinguish these influences from those related to metabolic phenomena associated with enzymatic and other similar reactions. For example a decrease in the  $Na$  count in the blood serum may be due to an increase in volume of body water and not to an increased rate of renal excretion of the isotope or an increased rate of excretion of  $Na$  may be due not to a change in sodium metabolic phenomena within the body but to an increased intake in regular sodium within the diet.

For a more thorough understanding of the quantitative and qualitative nature of some important factors independent of purely metabolic processes which influence concentration and total quantity of the tracer substance, certain interesting and essential theorems were devised.

#### MATHEMATICAL CONSIDERATIONS

If we consider the organism as a tank the mathematical theories outlined below will hold, regardless of the complex metabolic processes (physical and

chemical) within the organism. The equations are general and apply to any type of tracer studies within the limitations of the assumptions.

*Symbols —*

$t$  = time

$M_t$  = quantity of *nontracer* substance in organism at time  $t$

$M_o$  = quantity of *nontracer* substance in organism initially

$I$  = quantity of *nontracer* substance taken into organism per unit time

$G$  = net quantity of *nontracer* substance gained by organism per unit time (negative  $G$  = loss)

$K$  = quantity of *nontracer* substance eliminated from organism per unit time

$D$  = total amount of *nontracer* substance obtained under the condition of accumulation

$a$  = fraction of *nontracer* substance in organism eliminated from organism at any time  $t$  an expression of the rate of elimination

$\alpha$  = fraction of difference between maximum of the *nontracer* substance to be reached and amount present at time  $t$  an expression of the rate of accumulation

$N_t$  = quantity of *tracer* substance in organism at time  $t$

$N_o$  = quantity of *tracer* substance in organism initially

$V_t$  = volume of compartment under study at time  $t$

$V_o$  = initial volume of compartment under study

$CM$  = concentration of *nontracer* substance in organism (constant)

$CN_t$  = concentration of *tracer* substance in organism at time  $t$

$CN_o$  = concentration of *tracer* substance in organism initially

*Assumptions*

1. Tracer and *nontracer* substances are uniformly mixed in the organism and are affected similarly by chemical and physical processes in the organism.

2. All the *tracer* substance is added at time  $t = 0$  (initially) and is rapidly mixed completely with the *nontracer* substance.

3. Intake and discharge are continuous processes.

a. If the quantity of *nontracer* substance in the organism decreases, the change is expressed by

$$M_t = M_o e^{-at} \quad (1)$$

b. If the quantity of *nontracer* substance in the organism increases, the change is expressed by

$$M_t = M_o + D(1 - e^{-at}) \quad (2)$$

4. The change of the quantity of the *nontracer* substance and of the volume of its compartment is assumed to vary exponentially, since this is a physiologic variation which has been observed in our studies.

5. The solution of *nontracer* substance is always isotonic, therefore, in 3a,

$$V_t = V_o e^{-at}$$

and in 3b,

$$V_t = V_o + D(1 - e^{-at}) = \frac{V_o}{M_o} [M_o + D(1 - e^{-at})] \quad (2a)$$

Three conditions were analyzed

*First*, what are the variations with time in the concentration and total quantity of the tracer substance when the nontracer substance is in a negative balance, that is, when the rate of output exceeds the rate of intake?

Since the nontracer substance decreases,  $M_t = M_0 e^{-at}$ . In this case

$$G = \frac{dM_t}{dt} = -aM_0 e^{-at} \quad (3)$$

and

$$I = K + G = K - aM_0 e^{-at} \quad (4)$$

or

$$K = I + aM_0 e^{-at} \quad (5)$$

The discharge of the tracer substance from the organism per unit time is

$$\frac{dN_t}{dt} = -K \frac{N_t}{M_t} = -(I + aM_0 e^{-at}) \frac{N_t}{M_0 e^{-at}} = - \left[ \frac{I}{M_0} e^{at} + a \right] N_t \quad (6)$$

or

$$\frac{dN_t}{dt} + \left[ \frac{I}{M_0} e^{at} + a \right] N_t = 0 \quad (7)$$

The solution of this first order linear differential equation is

$$N_t = A e^{- \int \left( \frac{I}{M_0} e^{at} + a \right) dt} = A e^{- \left( \frac{I}{M_0} \frac{1}{a} e^{at} + at \right)} \quad (8)$$

where  $A$  is the integration constant

Since  $N_t = N_0$  when  $t = 0$ ,  
therefore,

$$N_0 = A e^{- \left( \frac{I}{M_0} \frac{1}{a} + 0 \right)} = A e^{- \frac{I}{aM_0}}$$

or

$$A = N_0 e^{\left( \frac{I}{M_0} \frac{1}{a} \right)} \quad (9)$$

Consequently

$$N_t = N_0 e^{- \left( \frac{I}{M_0} \frac{1}{a} + at \right)} = N_0 e^{- \left[ \frac{I}{M_0} \frac{1}{a} (1 - e^{-at}) \right]} \quad (10)$$

and

$$CN_t = \frac{N_t}{V_t} = \frac{N_0 e^{- \left[ \frac{I}{M_0} \frac{1}{a} (1 - e^{-at}) \right]}}{V_0 e^{-at}} = CN_0 e^{- \left[ \frac{I}{M_0} \frac{1}{a} (1 - e^{-at}) \right]} \quad (11)$$

*Second*, what are the variations with time in the concentration and in total quantity of the tracer substance when the nontracer substance is in a *positive balance*, that is, when the rate of intake of the substance exceeds the rate of output?

Since nontracer substance increases,  $M_t = M_0 + D(1 - e^{-\alpha t})$  In this case

$$G = \frac{dM_t}{dt} = \alpha D e^{-\alpha t} \quad (12)$$

and

$$I = K + G = K + \alpha D e^{-\alpha t} \quad (13)$$

or

$$K = I - \alpha D e^{-\alpha t} \quad (14)$$

The discharge of the tracer substance from the organism per unit of time is

$$\frac{dN_t}{dt} = -K \frac{N_t}{M_t} = -(I - \alpha D e^{-\alpha t}) \frac{N_t}{M_0 + D(1 - e^{-\alpha t})} \quad (15)$$

or

$$\frac{dN_t}{dt} + \frac{I - \alpha D e^{-\alpha t}}{M_0 + D(1 - e^{-\alpha t})} N_t = 0 \quad (16)$$

The solution of this first order linear differential equation is

$$N_t = A e^{-\int \frac{I - \alpha D e^{-\alpha t}}{M_0 + D(1 - e^{-\alpha t})} dt} \quad (17)$$

where A is the integration constant. The integral may be separated into two parts which are standard forms available in integral tables to give

$$N_t = A e^{-\frac{I}{M_0 + D} t - \left[ \frac{I}{(M_0 + D)\alpha} - 1 \right] \log_e |M_0 + D(1 - e^{-\alpha t})|} \quad (18)$$

Since  $N_t = N_0$  when  $t = 0$ ,  
therefore

$$N_0 = A e^{-\left[ \frac{I}{(M_0 + D)\alpha} - 1 \right] \log_e M_0} \quad (19)$$

or

$$A = N_0 e^{\left[ \frac{I}{(M_0 + D)\alpha} - 1 \right] \log_e M_0} = N_0 M_0^{\left[ \frac{I}{(M_0 + D)\alpha} - 1 \right]} \quad (20)$$

Consequently

$$N = N_0 e^{\left[ \frac{I}{(M+D)\alpha} - 1 \right] \log M - \frac{I}{M+D} t} = \left[ \frac{I}{(M+D)\alpha} - 1 \right] \log [M + D (1 - e^{-\alpha t})] \\ = N_0 M^{\frac{I}{(M+D)\alpha} - 1} [M + D (1 - e^{-\alpha t})]^{-\left[ \frac{I}{(M+D)\alpha} - 1 \right]} e^{-\frac{I}{M+D} t} \quad (21)$$

and

$$CN_t = \frac{N_t}{V_t} = \frac{N_0 M^{\frac{I}{(M+D)\alpha} - 1} [M + D (1 - e^{-\alpha t})]^{-\left[ \frac{I}{(M+D)\alpha} - 1 \right]} e^{-\frac{I}{M+D} t}}{\frac{V}{M} [M + D (1 - e^{-\alpha t})]} \\ = CN_0 M^{\frac{I}{(M+D)\alpha}} [M + D (1 - e^{-\alpha t})]^{-\frac{I}{(M+D)\alpha}} e^{-\frac{I}{M+D} t} \quad (22)$$

*Third*, what are the variations with time in the concentration and total quantity of the tracer substance when the nontracer substance is not changing in amount within the organism that is when intake and output are equal?

Since the nontracer substance does not change  $M_t = M_0$ . In this case

$$G = \frac{dM_t}{dt} = 0 \quad (23)$$

and

$$I = K + G = K \quad (24)$$

The discharge of the tracer substance from the organism per unit of time is

$$\frac{dN_t}{dt} = -K \frac{N_t}{M} = -\frac{I}{M} N_t$$

or

$$\frac{dN_t}{dt} + \frac{I}{M} N_t = 0 \quad (25)$$

The solution of this linear differential equation with the condition  $N_t = N_0$  when  $t = 0$  is

$$N = N_0 e^{-\frac{I}{M} t} \quad (26)$$

Therefore

$$CN_t = \frac{N}{V_t} = \frac{N_0 e^{-\frac{I}{M} t}}{V} = CN_0 e^{-\frac{I}{M} t} \quad (27)$$

## DISCUSSION OF EQUATIONS

So that the significance of the equations may be appreciated, certain theoretic considerations are presented. Because the present studies are concerned with tracing sodium following a single injection of radiosodium ( $\text{Na}^{22}$ ) in normal man and in man with generalized edema due to congestive heart

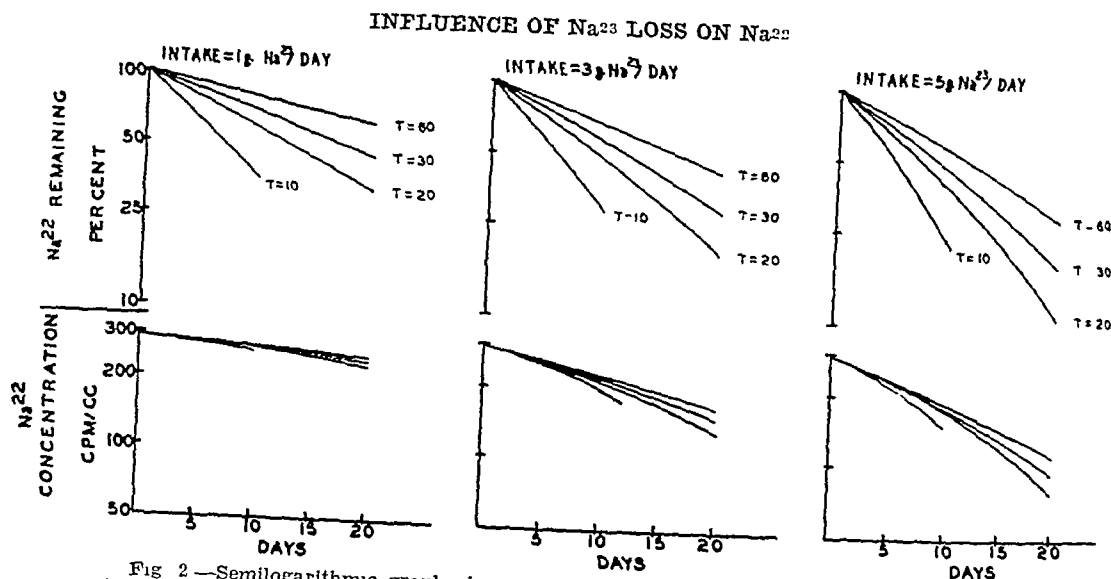

Fig 2 —Semilogarithmic graph showing the influence of the net loss of  $\text{Na}^{23}$  on the  $\text{Na}^{22}$  content of the body after administration of a single dose of the tracer. The influence of the rate of  $\text{Na}^{23}$  intake upon the  $\text{Na}^{22}$  is indicated.  $T$  denotes the time in days required for an edematous individual with a total of 121.4 grams of  $\text{Na}^{23}$  in the body to become edema-free and for the  $\text{Na}^{23}$  content to be reduced to 50 grams. The upper group of curves shows the time variations in the percentage of the initial  $\text{Na}^{22}$  remaining in the body and the lower group of curves indicates the time variations in concentration of the  $\text{Na}^{22}$ . The  $T$  values follow the same order for the lower group of curves as indicated for the upper ones. For the curve showing rapid rate of  $\text{Na}^{23}$  loss or rapid rate of elimination of edema ( $T = 10$  days) the patient reached the edema-free state in ten days and the curve therefore does not extend as far on the abscissa as do those curves for the other rates. It is interesting to note that the curves are *not* straight lines. For convenience the other curves were not continued beyond twenty days if they were extended until the subject became edema-free the amount of  $\text{Na}^{22}$  remaining in the body would be progressively less as the value of  $T$  increased.

failure, it would be interesting and enlightening to apply the equations formulated to certain theoretic situations, such as man with generalized edema who is losing it rapidly, normal man developing edema, and man whose state of electrolyte and water balance is stationary, and to determine the time variations in  $\text{Na}^{22}$  in the body in these three conditions.

*Application 1* —Man with generalized edema such that his total  $\text{Na}^{23}$  mass is 121.4 grams (his total extracellular fluid mass 34,000 grams), his edema is progressively decreasing, and the sodium ( $\text{Na}^{23}$ ) and extracellular fluid masses for a man weighing 70 kilograms (50 and 14,000 Gm respectively) are finally reached.

For better comprehension of the influence of the rate of elimination or discharge of  $\text{Na}^{23}$  upon the concentration and total amount of  $\text{Na}^{22}$  present within the body, the rate with which the subject theoretically became free from edema

was varied for different rates of sodium intake. The output of water was assumed to vary during the defined circumstances to maintain isotonicity.

Figs 2 and 3 show the theoretic progressive change in the total amount and in the concentration of  $\text{Na}^{22}$  in the extracellular fluid for rates of excretion which would make the subject free of edema in ten, twenty, thirty, and sixty days when the daily intake of sodium ( $\text{Na}^3$ ) was 1, 3 or 5 grams.

Fig 3—The individual curves shown in Fig 2 grouped to show better the relationship of the time variations of concentration of  $\text{Na}^{22}$  to the time course of the percentage of an initial single quantity of administered  $\text{Na}^{22}$  not eliminated.

These two figures reveal several things

(a) When the intake of  $\text{Na}^3$  remains constant, its rate of elimination so influences the  $\text{Na}^{22}$  in the extracellular fluid that measurements solely of the concentration of  $\text{Na}^{22}$  in the blood serum cannot serve as an index of the amount of  $\text{Na}^{22}$  still remaining in the body. A small decrease in the concentration of  $\text{Na}^{22}$  is associated with a relatively large total elimination of  $\text{Na}^{22}$ . This is to be expected since water is being lost simultaneously at a rate which maintains isotonicity of the  $\text{Na}^{22}$ .

(b) Differences in the rate with which  $\text{Na}^3$  is eliminated from the subject are accompanied by less change in the concentration of the  $\text{Na}^{22}$  in the extracellular fluid than in total quantity of  $\text{Na}^{22}$  present within those fluids. This is reasonable, since water is being eliminated with the  $\text{Na}^3$  to maintain isotonicity.

(c) The rate of  $\text{Na}^{23}$  intake has a greater influence upon the change in concentration of  $\text{Na}^{22}$  in the extracellular fluids than does the rate of elimination of the edema. This is well illustrated by Fig. 3 for the daily intake of 1 and 5 grams. A greater intake of  $\text{Na}^{23}$  results in a more rapid rate of elimination of  $\text{Na}^{22}$  as well as in a sharper rate of decline in concentration of  $\text{Na}^{22}$  in the extracellular fluids. This effect of  $\text{Na}^{23}$  intake upon  $\text{Na}^{22}$  must exist, because the rate of elimination of the former must increase in order to produce the edema.

#### INFLUENCE OF $\text{Na}^{23}$ GAIN ON $\text{Na}^{22}$

Fig. 4.—Semilogarithmic graph showing the influence of the *net gain* of  $\text{Na}^{23}$  on the  $\text{Na}^{22}$  content of the body after the administration of a single dose of the tracer. The influence of the rate of  $\text{Na}^{23}$  intake upon the  $\text{Na}^{22}$  is indicated.  $T'$  denotes the time in days required for the total sodium of a *nonedematous individual* to increase from 50 grams to 121.4 grams when an arbitrary maximum of edema is reached. The labeling scheme is the same as used in Fig. 2. Each curve is not a straight line for obvious reasons. Values of  $T'$  smaller than those shown could not be analyzed under the conditions of the calculations (see text). Note the inverse relationship in the order on the ordinate positions of the curves for the respective  $T'$  and  $T$  values of this figure and that of Fig. 2.

free state at the given time. Since the movement of the  $\text{Na}^{22}$  is determined by the movement of the  $\text{Na}^{23}$ , then a greater intake of  $\text{Na}^{23}$ , with a resulting increased elimination of  $\text{Na}^{23}$ , must produce an increase in the rate of elimination of  $\text{Na}^{22}$ .

(d) The elimination of  $\text{Na}^{22}$  under the circumstances described is not a *simple* exponential phenomenon.

(e) It is evident from the equations and from Figs. 2 and 3 that when the subject is losing edema, the rate of excretion of  $\text{Na}^{23}$  is of paramount importance in influencing the  $\text{Na}^{22}$  content of the body, since the volume of the extracellular fluid decreases at a rate which insures isotonicity. The rate of  $\text{Na}^{23}$  intake is influential because of its effect upon its own rate of elimination.

(f) When a subject is progressively excreting the nontracer substance under the conditions defined, the rate of change in the total *amount* of the tracer substance retained is greater than the rate of change in *concentration* of the tracer. This is to be expected from equations (10) and (11). It must be remembered

that the volume of the compartment of the tracer and nontracer substances is diminishing progressively as the  $\text{Na}^{23}$  is being eliminated

(g) The  $\text{Na}^{23}$  concentration in the extracellular fluids is constant a necessary condition since isotonicity is essential for life.  $\text{Na}^{23}$  concentration however is not constant, because  $\text{Na}^{23}$  is gradually being eliminated from the body without any associated continuous addition

#### INFLUENCE OF $\text{Na}^{23}$ GAIN ON $\text{Na}^{22}$

Fig 5—The individual curves shown in Fig 4 grouped to show better the relationship of the time variations of concentration of  $\text{Na}^{22}$  to the time course of the percentage of an initial single quantity of administered  $\text{Na}^{22}$  not eliminated

*Application 2*—An edema free man weighing 70 kilograms whose total  $\text{Na}^{23}$  mass is 50 grams (his total extracellular fluid mass is 14 000 grams), and in whom edema is progressively developing until a sodium ( $\text{Na}^{23}$ ) and extracellular fluid masses of 121.4 grams and 34,000 grams respectively are finally reached. Isotonicity is assumed to be maintained.

The intakes of  $\text{Na}^{23}$  and water in this man were observed from a theoretic point of view to learn their effects upon the  $\text{Na}^{22}$  concentration in the extracellular fluids and upon the rate of elimination of  $\text{Na}^{22}$ . The influences of the rate of excretion of  $\text{Na}^{23}$  upon the time variations in concentrations of the  $\text{Na}^{22}$  and upon the rate of elimination of  $\text{Na}^{22}$  in a subject in whom edema is progressively increasing are summarized in Figs 4 and 5. These calculations yield the following information:

(a) A subject cannot acquire edema and accumulate sodium at a rate faster than the intake except where special consideration must be given to storage depots and local shifts. For this reason daily intake of 1 gram of  $\text{Na}^{23}$

could not be studied for the rates of formation of edema considered to exist in these calculations. It was also impossible to study the condition when maximum edema was realized in ten days, as such a limit could not have been reached in this time even when the daily intake of  $\text{Na}^{23}$  was 5 grams. Therefore, the rate with which it is possible for edema to develop is dependent on the rate of intake of sodium.

#### INFLUENCE ON $\text{Na}^{22}$ , AMOUNT OF $\text{Na}^{23}$ CONSTANT

Fig. 6 — Semilogarithmic graph showing the influence of no change in the total  $\text{Na}^{23}$  upon the  $\text{Na}^{22}$  content of the body after administration of a single dose of the tracer. Although the total amount of  $\text{Na}^{23}$  does not change  $\text{Na}^{23}$  is being taken into the body and also being eliminated at rates of 1, 3, and 5 grams daily. These curves are all straight lines for obvious reasons.

(b) When  $\text{Na}^{23}$  is being accumulated during progressive formation of edema, the rate of decrease in concentration of the  $\text{Na}^{22}$  exceeds the rate of change in total content of the tracer within the body. This is to be expected, since the concentration of  $\text{Na}^{22}$  is being reduced by *two* factors acting simultaneously.

(1) Accumulation of fluid of edema, which produces a *dilution effect* on the  $\text{Na}^{22}$ .

(2) *Continuous elimination of  $\text{Na}^{22}$* 

Reduction in the total content of  $\text{Na}^{22}$  within the body on the other hand results only from continuous elimination of  $\text{Na}^{22}$ .

(c) Intake of  $\text{Na}^{22}$  and its resultant output has a greater influence on the  $\text{Na}^{22}$  concentration and total content within the body than the rate of the development of the edema.

*Application 3*—Man whose electrolyte and water balance are stationary.

For the special situation in which there is no gain or loss of  $\text{Na}^{22}$  in the body and in which the extracellular fluid remains isotonic, the rate of elimination of  $\text{Na}^{22}$  becomes all important. The rate of intake is significant because of its direct influence upon excretion. When  $G$  is equal to zero, then intake and output must be equal.

Results of these calculations are shown in Fig. 6, which shows that

(a) The greater the elimination and, therefore intake of  $\text{Na}^{22}$ , the greater the elimination of  $\text{Na}^{22}$ . This follows because the movement of the non tracer substance determines the movement of the tracer.

(b) When  $G$  is equal to zero, the rates of intake and output have no greater influence on the change in concentration of the tracer,  $\text{Na}^{22}$ , than they have on the change in total quantity of the tracer. This is obvious from equations (26) and (27).

(c) When  $G$  is equal to zero and the tracer substance is not fixed in any manner in the organism, the  $B_1$ ,  $C_{1/2}$ , and  $E_{1/2}$  (time required to eliminate one half of the tracer) are equal.

(d) When  $G$  is equal to zero the decay curves for concentration and for total quantity of the tracer remaining in the organism are parallel and straight lines on semilogarithmic graph paper. These are simple exponential curves.

## GENERAL DISCUSSION

From the preceding discussions and calculations it is obvious that when a tracer is employed to study a substance in an organism, the rate of excretion of the nontracer substance will affect the concentration and quantity of the tracer substance. This is true regardless of changes in size of the nontracer compartment. Factors which influence the elimination of the nontracer must be properly controlled if other physiologic phenomena are to be accurately evaluated. Variations in size of the compartment for the nontracer substance must also be properly controlled and evaluated.

The situations herein discussed were sharply defined and controlled in these calculations, but such is not possible in the average living organism. The intake of the nontracer substance is not uniform at all times; it usually occurs three or four times a day at an irregular rate. Therefore, its rate of elimination is not constant from hour to hour and from day to day. With disease, this irregularity may be even more pronounced. For example, Fig. 7 illustrates the relationship of changes in  $\text{Na}^{22}$  to  $\text{Na}^{22}$  in a man whose sodium is being studied with  $\text{Na}^{22}$  as a tracer. During the first ten days he is free from edema and his intake and output of  $\text{Na}^{22}$  and water are equal. During the next thirty days he retains

$\text{Na}^{23}$  and water, and edema progressively develops, during the following ten days, as his intake and output of  $\text{Na}^{23}$  and water again become equal, his edematous state remains stationary, during the ensuing thirty days his output of  $\text{Na}^{23}$  and water exceed the intake, so that the edema progressively diminishes, and finally he again has an equal intake and output of  $\text{Na}^{23}$  and water while in

Fig 7—Combination curves illustrating the influence on the concentration of  $\text{Na}^{22}$  and total content of  $\text{Na}^{22}$  in the body for an individual who is normal and edema-free for ten days in whom edema then progressively develops for the next thirty days and who remains at a stationary edematous level for ten days gradually becomes edema-free in thirty days and remains so for ten more days. Consult the text for details.

the state free of edema. Curves showing simultaneous variations in concentration and quantity of  $\text{Na}^{22}$  and of  $\text{Na}^{23}$  content within the body are shown. Irregularities in rates of change are attributable to combinations of the three situations previously calculated. Since it is theoretically possible for the time intervals shown on the abscissa to vary from minutes to months, then it is obvious that biologic studies often constitute averages and not detailed absolute values. The conditions are seen to be even more complex when it is realized that all of these and other factors may be acting and varying simultaneously. These data demonstrate the advisability of meticulously controlled biologic experiments.

Complexity of the biologic conditions of experimentation is further evidenced by the fact that absolute equilibrium is relatively rare, if ever present. Furthermore the compartments of the substance under study are not uniform in size, behavior, or constitution, they actually constitute many different compart-

ments within a large one. The behavior of many of the substances traced is under the influence of complex metabolic processes, such as enzymatic reactions further emphasizing the need for great caution in biologic experimentation and in interpretation of data.

### COMPARISON OF THEORETIC WITH EXPERIMENTAL

Fig 8—Comparison of the theoretic curves of the concentration of  $\text{Na}^{24}$  and total content of  $\text{Na}^{24}$  in the body of a normal man with data obtained experimentally in two normal subjects. The nonurinary  $\text{Na}^{24}$  is that not excreted in the urine and is represented as percentage of the total  $\text{Na}^{24}$  injected intravenously into the subject at a single dose. For the theoretic curve it represents the percentage of the total  $\text{Na}^{24}$  which is not excreted and remains within the body. Values for intake of  $\text{Na}^{24}$  selected for the theoretic curves were those which approximated the dietary intake in the subjects studied. The theoretic and experimental curves agree remarkably well. Discrepancies between the nonurinary  $\text{Na}^{24}$  curves are due to failure to collect all excretion from the subjects studied experimentally. The experiments were designed for urinary collection alone.

It is well to emphasize that it is easier to trace elements than complex substances or formed tissue structures, such as cells which enter into metabolic processes and turnover phenomena independent of the element traced. For example, an amino acid tagged with an isotope in which the isotope is followed may lead to difficulties because the isotopic form can be removed from the amino acid molecule and therefore no longer tag the amino acid. The same holds true for cells, as for example, tracing erythrocytes by means of  $\text{P}^{32}$ ,  $\text{Fe}^{55}$  or  $\text{N}^{15}$ . The last of these is the best, since it will remain in the erythrocytes until they disintegrate, whereas the first is least serviceable, since it diffuses out so readily with or without associated metabolic processes.

Obviously, the data herein presented are only theoretic indicating the behavior of the tracer substance under the conditions described, and should be

compared with actual biologic experiments only with extreme caution. Nevertheless, it is possible to note a similarity in the curves of the calculations of the theoretic status and those observed with  $\text{Na}^{22}$  in normal subjects and in subjects with congestive heart failure (Fig. 8). That changes in concentration of  $\text{Na}^{22}$  varied with intake of  $\text{Na}^{23}$  and progress of the edema is evident. Unfortunately, the excretion of  $\text{Na}^{22}$  was measured only in the urine and the total  $\text{Na}^{23}$  output was not determined. Such experiments should be conducted.

In the calculations of  $\mathbf{N}_t$  the entire loss of  $\text{Na}^{22}$  from an organism was accounted for, therefore when  $\mathbf{N}_t$  for  $\text{Na}^{22}$  is equal to one-half of  $\mathbf{N}_0$ , then  $t$  is the *overall* or *absolute*  $B_{1/2}$  for the organism. Close inspection of the graphs of the  $\mathbf{N}_t$  values reveals variations in the time course of  $\mathbf{N}_t$  and therefore  $B_{1/2}$  varies from moment to moment within limiting conditions of the calculations. On the other hand the  $U_{1/2}$  values obtained by experimentation cannot be employed as direct values of  $B_{1/2}$  because the  $U_{1/2}$  values are based only upon urinary excretion of  $\text{Na}^{22}$ .

#### SUMMARY

Equations have been derived which make it possible to predict the influence of variations of intake and output of a nontracer substance and of the size of its compartment upon the concentration within the organism and elimination from the organism of a tracer substance administered in a single dose. These theoretic considerations demonstrate the extreme importance of controlling and properly evaluating factors which affect the rate of elimination and the size of the compartment of the nontracer substance. The need and reasons for exercising every caution in interpretation of data concerned with measuring variations in concentration and total content of the tracer substance are emphasized.

Although the discussion is chiefly concerned with problems for sodium tracer studies, these theoretic considerations apply to any type of tracer experiments, regardless of size or location of the compartment and regardless of whether the tracer is stable or radioactive. It is hoped that the mathematical considerations will be of value to others engaged in biologic and nonbiologic tracer research.

# THE NATURE OF THE ALTERED RENAL FUNCTION IN LOWER NEPHRON NEPHROSIS

DANIEL MARSHALL, M.D., AND WILLIAM S. HOFFMAN, M.D., PH.D.  
CHICAGO, ILL.

LOWER nephron nephrosis is a term proposed by Lucet<sup>1</sup> to describe a syndrome of oliguria with progressive renal insufficiency following a shock like state produced by a variety of acute insults to the body and in many cases associated with the deposition in the renal tubules of various derivatives of hemoglobin and myoglobin. Pathologically, the principal renal lesion is degeneration and necrosis of the epithelium of the ascending loops of Henle and the distal convoluted tubules. We have recently developed a regimen for the management of such patients with lower nephron nephrosis by means of which we were able to keep five out of six patients alive until the kidneys recovered spontaneously and reversed the retention of excretory products. Four patients recovered completely, the fifth still has a residual renal lesion and the sixth died in uremia with heart failure five days after diuresis had set in. The management and the clinical course as well as the detailed serum and urinary chemical findings in these six cases are described elsewhere.

In three of the surviving patients kidney function was studied during the diuretic and recovery periods by means of the specific renal function tests described by Homer Smith and colleagues.<sup>2</sup> Included were serial determinations of the clearances of mannitol, *p*-aminohippurate, creatinine, and urea and of the tubular excretory mass all performed essentially by the technique described by Goldring and Chasis,<sup>4</sup> except that mannitol was analyzed by the method of Coreoran and Page.<sup>5</sup> The data from these tests obtained during the period of progressive recovery, in addition to the information obtained regarding urinary nitrogen excretion, can in a way be extrapolated back to the period of oliguria and thus provide some insight into the pathologic physiology of the disease.

## RESULTS

The essential clinical features of the six cases are summarized in Table I. It will be seen that the oliguria persisted from five to thirteen days. In the adults it was recognized that once 500 cc of urine were excreted daily, the output thereafter rose rapidly to high levels. The onset of diuresis was accordingly dated from the day 500 cc were first excreted.

Figs. 1, 2, and 3 show the relationship between urinary excretion of water and excretory nitrogen and the serum levels of nonprotein nitrogen in Cases 3, 4, and 5. The tendency for the serum nonprotein nitrogen to level off in spite of the continued intake of protein was either a manifestation of the dilution of retention products produced by the increase in extracellular fluid

volume, reflected by gross edema which was deliberately fostered, or of a diminution in cellular breakdown as the bodily nutrition was improved under the management. It can be seen that the initial days of diuresis were associated with the excretion of relatively small quantities of nitrogen, the concentration ratio of urinary to serum nonprotein nitrogen tending to remain as low as

Fig 1—Urinary output of water and nitrogen in Case 3 in relation to serum nonprotein nitrogen concentration and to the ratio of urinary to serum nonprotein nitrogen concentration

during the oliguria period. For this reason, the peak level of serum nonprotein nitrogen was usually not reached until diuresis was well under way. It was only as the diuresis continued to improve (with daily excretions reaching a value of 9,900 cc in Case 5) that the concentration ratio increased. The excretion of nitrogen soon became great enough to produce a rapid fall in the serum nonprotein nitrogen concentration.

Table II shows the absolute values for the various renal functions in Cases 3, 4 and 5. Values for glomerular filtration and effective renal plasma flow were very low at the time of the first test in spite of the fact that these tests were performed when the patients already had improved considerably. Selkurt<sup>6</sup> has demonstrated experimentally that during hemorrhagic shock direct measurements of renal plasma flow give values appreciably higher than those obtained by the determination of *p* aminohippurate clearance. This evidence suggested

that values for mannitol and *p*-aminohippurate clearances were not true measures of the rates of glomerular filtration and renal plasma flow respectively in kidneys as severely damaged as those of our patients. Certain aspects of our data amply confirmed this suspicion. For example, Table II shows that the filtration fraction, as measured by the ratio of the mannitol to the *p* amino hippurate clearance, was in Case 3 greater than 1 instead of the normal 0.20

Fig 2—Urinary output of water and nitrogen in Case 4 in relation to serum nonprotein nitrogen concentration and to the ratio of urinary to serum nonprotein nitrogen concentration

Such a finding is, of course, an absurdity. In Case 4, the first filtration fraction was 0.64, a value impossibly high. In Case 5, the first filtration fraction was the normal 0.20, which we believe was due to the fact that the function tests were performed relatively late in a subject who was very rapidly improving.

A further indication of lack of absolute significance of the values in these first tests is the first determination of tubular excretory mass ( $T_m$ ). In Cases 3 and 4 the values were less than zero, which meant that the *p*-aminohippurate excreted by the glomeruli alone—as measured from the mannitol clearance—was greater than the sum of glomerular and tubular excretion as calculated from the total *p* aminohippurate excreted. When this unusual finding was obtained in the first subject it was thought to be due to a technical error. But a second

such result in Case 4 made that explanation unlikely. It was at this time that the paper by Redish and colleagues appeared in which a negative Tm was also reported in their single case. The validity of these analyses was thus further confirmed.

Fig. 3—Urinary output of water and nitrogen in Case 3 in relation to serum nonprotein nitrogen concentration and to the ratio of urinary to serum nonprotein nitrogen concentration.

Table II also demonstrates still another absurd relationship arising out of the distorted clearance and excretion values during the early stages of recovery. The ratio of the *p* aminohippuric clearance to the tubular excretory mass which normally lies between 7 and 9 and which is a measure of the relative blood supply to the functioning renal tissue was in Cases 3 and 4, infinitely high because the tubular excretory mass was zero or less than zero. On the other hand, in Case 5 the initial value was only slightly higher than normal.

Fig. 4 shows in graphic form the relative rates of restitution of the clearance and tubular mass values toward normal. The distorted relationships found in the first tests disappeared in the subsequent determinations. A week after the first test the tubular mass was no longer negative and the filtration fraction and ratio of *p* aminohippuric to Tm had returned to nearly normal values in Cases

Fig 4—Relative rates of restitution to normal of the specific renal functions tests in Cases 3, 4 and 5

4 and 5 and were improving rapidly in Case 3. By the next week, the distortion disappeared even in Case 3. On the other hand complete functional restitution to normal occurred more slowly than would be expected from the rapidity of clinical recovery. It required three months in Case 5 and nearly seven months in Cases 3 and 4. In the child of 2 years (Case 6), a residual renal insufficiency was still manifest at four months the nature of which has not been ascertained. In the patient of Redish mentioned previously, complete return to normal function was not seen before two years.

Urea clearance values returned to normal at essentially the same rates as did mannitol and *p* aminohippurate clearances. This finding is of practical importance for it signifies that the more readily determined urea clearances can be just as satisfactorily utilized as a clinical guide to the rate of recovery in this disease as the more elaborate renal function tests. Creatinine clearances improved more rapidly than any other clearance. The reason for this is not clear.

#### DISCUSSION

These unusual results of the specific renal function tests in the early period of recovery can be explained by the loss of the specific function of the lower

nephron to resorb water or sodium and to produce ammonia, thereby forming a concentrated and acidified urine. Instead the tubular cells in this region are so badly damaged that they allow the nonspecific osmotic resorption of most of the modified glomerular filtrate that reaches them, thus leaving little or no filtrate to be excreted as urine. What little urine is excreted during the oliguric phase has a specific gravity not much different from that of glomerular filtrate and is nearly neutral in reaction. The urine obtained during the first days of diuresis is only a larger quantity of the same type of fluid with little or no increase in concentration of the excretory products. It thus appears that the beginning of diuresis is brought about by an increase in glomerular filtration (and effective renal blood flow) without any recovery as yet of specific function of the lower nephron. This increased flow may be brought about by subsidence of renal swelling, as suggested by Coicoran, Taylor, and Page,<sup>8</sup> or by disappearance of the shunt through nonfiltering glomeruli into the medulla.

The tubular defect is apparently associated with a gradient diffusion of the constituents of the glomerular filtrate. With a high concentration of *p* aminohippurate in the glomerular filtrate and a low concentration in the tubular blood supply (if the excretory function of the proximal convoluted tubules has not been impaired), the *p* aminohippurate is resorbed by the damaged lower nephron to a greater extent than mannitol, the concentration of which is nearly the same in the filtrate as in the tubular blood. As a consequence less *p* aminohippurate may appear in the urine than mannitol in proportion to their respective blood levels. Thus the tubular mass value becomes negative, and the filtration fraction greater than 1. This gradient diffusion appears to be the first tubular defect to recover, as indicated by a return to nearly normal values for filtration fraction and for the ratio of *p*-aminohippurate to tubular mass long before the individual clearances have reached normal. It is reasonable to believe that the improvement in effective renal blood flow is itself responsible for the accelerated tubular repair. The complete recovery of normal renal function in four of our patients and in that of Redish indicates that the glomeruli were never completely blocked and that the tubules always had sufficient blood supply to prevent irreversible destructive changes.

#### SUMMARY AND CONCLUSIONS

Serial determinations of clearances of mannitol, *p* aminohippurate, urea, and creatinine and of tubular excretory mass were carried out in three subjects in the phase of diuresis and recovery from lower nephron nephrosis.

In two subjects, the first test gave negative values for tubular excretory mass and impossibly high values for filtration fraction and ratio of *p* aminohippurate clearance to tubular excretory mass. In subsequent tests these distortions disappeared but complete restitution of renal function did not occur until three to seven months had elapsed.

These data along with the findings on the rate of excretion of nitrogen and water during the oliguric and diuretic periods are consonant with the idea that the renal lesion in lower nephron nephrosis is a diminished renal blood flow in association with a loss of specific function of the lower nephron. Consequently,

the limited amount of modified glomerular filtrate reaching the lower nephron is almost completely reabsorbed. A gradient diffusion through the damaged cells appears to be present which is responsible for the distorted renal clearance tests. Recovery seems to be produced first by an increase in effective renal blood flow followed later by repair of tubular function. The gradient diffusion is apparently the first tubular defect to disappear. The total recovery of normal tubular function is much slower.

The authors acknowledge with thank the assistance of Mrs Catherine Nobe and Miss Lorraine Schmelzle with the chemical analysis.

## HISTOPATHOLOGY OF THE LIVER IN HUMAN BRUCELLOSIS

WESLEY W SPINK, M D, FREDERICK W HOFFBAULR, M D,  
WALTER W WALKER, M D, AND ROBERT A GREEN, M D  
MINNEAPOLIS, MINN

THE histopathology of brucellosis has been defined for the most part on the basis of studies of the tissues in experimentally infected animals, and the tissues of patients who, having had the disease, died from brucellosis or other causes. Little information is available relative to the tissue reactions that occur in the ambulatory patient with acute or chronic brucellosis. This report represents one aspect of a general study on the pathogenesis of human brucellosis being carried out in this clinic. In these investigations, the changes taking place in certain organs and tissues have been ascertained by obtaining specimens with biopsy techniques. Attention has been given particularly to those patients having bacteriologically proved brucellosis. Sundberg and Spink<sup>1</sup> already have described in detail the histopathology of the sternal bone marrow in human brucellosis. The purpose of this paper is to present the findings in the liver of eleven patients with proved brucellosis. While hepatic lesions have been described previously, there is a lack of knowledge of the changes that occur in living subjects who eventually recover from the disease.

Fabryan,<sup>2</sup> and later Jaffe,<sup>3</sup> emphasized the characteristic granulomatous lesion of brucellosis in experimentally infected guinea pigs. Some years later Löffler and von Albertini<sup>4</sup> described these granulomas in human material. Their initial observations were limited to a single case in which splenectomy and a liver biopsy were carried out. Subsequently, von Albertini and Lieberherr,<sup>5</sup> in one of the best discussions of the pathology of human brucellosis, detailed the findings in the liver and spleen. They observed granulomatous hepatic lesions with and without extensive necrosis. It is quite apparent from studying their paper that brucellosis cannot be distinguished from tuberculosis on the basis of the hepatic changes. The only illustration of a hepatic granulomatous lesion due to brucellosis that we have observed in the English or North American literature is in the paper by Mettler and Kerr.<sup>6</sup> A liver biopsy was secured from the left lobe of the liver at the time a cholecystectomy was performed. Microscopic examination revealed a bizarre, destructive, and inflammatory process in various stages. One large lesion with central necrosis was observed and adjacent to this there were numerous, discrete, tubercle-like foci which consisted of lymphocytes, epithelioid cells, and an occasional giant cell. In another instance Lowbeer<sup>7</sup> reported a case of brucellosis in which cholecystectomy was carried out and a biopsy of the liver was made. Granulomas were found in the wall of the gall bladder and in the liver.

From the Divisions of Internal Medicine and Pathology of the University of Minnesota Hospitals and Medical School.

This investigation was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, United States Public Health Service.

Received for publication Oct 2 1948

## METHODS OF STUDY

Specimen of liver were obtained from eleven cases of human brucellosis. The diagnosis of active disease was proved bacteriologically in eight of the eleven cases. In the remaining three patients the diagnosis was established on the basis of epidemiologic, clinical, and serologic evidence. Ten of the eleven patients recovered from the disease. One patient committed suicide and a complete post mortem study was obtained. The duration of the disease in this group varied between three weeks and three years. Biopsies of hepatic tissue in the living subjects were obtained by one of the three following methods: peritoneoscopy, needle biopsy, or surgical excision. The needle biopsy method is now employed exclusively since it is simple and can be carried out at the bed side. In addition to fixing and staining the specimens of liver, portions of the biopsied material in four instances were cultured for *Brucella*. Special stains were also carried out for connective tissue, reticulum, glycogen, and bacteria.

In an attempt to correlate the histologic changes in the liver with functional impairment of the organ, a series of liver function tests were performed in each case. A brief clinical history of each case is presented along with a description of the hepatic tissue. Pertinent chemical data, the liver function studies that revealed abnormal results and the cardinal histologic findings are summarized in Table I.

## RESULTS

CASE 1—F. H., a 28 year old housekeeper had been ill for four and one half months. Weakness was the original complaint. Then ensued severe shaking chills, drenching sweats and fever. The source of her infection was the ingestion of raw milk obtained from a herd of cattle having Bang's disease. On admission to the hospital the outstanding findings were an acutely ill and febrile patient with no demonstrable enlargement of the liver but a firm and nontender spleen was palpated at the left costal margin. Pertinent laboratory data revealed a leucocyte count of 6,400 with a differential of 68 per cent polymorphonuclear neutrophils, 38 per cent lymphocytes, and 4 per cent monocytes. The erythrocyte sedimentation rate was 72 mm in one hour (Westergren). Agglutinins for *Brucella* were present in the serum in a titer of 1 to 320 to 1 to 640. On four occasions *Brucella abortus* was isolated from cultures of blood.

Penicillin was administered in large doses without benefit but coincident with treatment with sulfadiazine, the patient improved. Subsequent blood cultures, however, showed the presence of *Br. abortus*. Because the patient was febrile and the splenic enlargement persisted, splenectomy was carried out, and a biopsy of the liver was made at the same time. The spleen weighed 217 grams. Multiple cultures of splenic tissue remained sterile, and microscopic studies showed numerous large granulomatous lesions. Subsequent hepatic function studies showed normal values. Splenectomy did not appear to improve her condition, and improvement occurred gradually over a period of several months.

*Study of Liver Biopsy* The specimen was a triangular fragment from the liver edge measuring 9 by 4 by 2 millimeters. Microscopically, the architectural pattern appeared normal. A few of the portal spaces contained a mild infiltration with small round cells. No excess of connective tissue could be demonstrated with the azocarmine stain. Scattered hepatic cells contained a small amount of finely divided golden brown pigment which did not stain for iron. A few degenerating cells were present, surrounded by polymorphonuclear leucocytes. Best's carmine stain showed a normal complement of glycogen. Three small granulomas were present, two located within one portal space and a smaller one within another portal space. They were similar in appearance with a peripheral zone of small lymphocytes and a central collection of epithelioid

TABLE I SUMMARY OF DATA ON ELEVEN CASES OF HUMAN BRUCELLA

CASE	AGE AND SEX	OCCUPATION	DURATION OF DISEASE	COMPLICATIONS	BACTERIOLOGY	TITER OF AGGLUTININS	ABNORMAL LIVER FUNCTION STUDIES*	LIVER BIOPSY
1	28 F	Housekeeper	1½ mo	None	Blood + (Br abortus 1 ×)	1 to 320 1 to 640 1 to 2,560	All normal Urine urobilinogen, 2 l Ehrlich units in 2 hr coproporphyrin, 119 g units per 24 hr	Granulomas in portal spaces Granuloma in lobules and portal spaces Langerhans giant cells
2	29 M	Farmer	11 mo	None	Blood + (Br abortus 2 ×)			
3	17 M	Confectioner	1 mo	None	Blood + (Br abortus 2 ×)	1 to 5,120	Urine urobilinogen, 36 Ehrlich units in 2 hr urine coproporphyrin, 337 g units in 24 hr, sulfthrombulem, 21 per cent retention	Granuloma in lobules and marked infiltration of round cells in portal spaces Patchy fatty metamorphosis
4	33 F	Housewife	22 mo	None	Blood - (ie peritely sterile cultures)	1 to 640	Serum bilirubin 1 mm 0.1 mg, total 1.1 mg	Granuloma with giant cell in lobules, occasional necrotic liver cells
5	66 F	Housewife	6 mo	None	Blood + (Br abortus 2 ×)	1 to 1,280	<i>First admission</i> Thymol turbidity, 8 units, urine coproporphyrin, 175 g units in 24 hr <i>Second admission</i> Sulfabromthalein, 6 per cent retention, cephalin cholesterol flocculation, 2+ in 24 hr, thymol turbidity, 16 units, urine urobilinogen, 52 mg per 24 hr, urine coproporphyrin, 153 g units per 24 hr	Marked lymphocytic infiltration of liver cells, scattered necrotic liver cells, granulomas in lobules

6	41	M	Truck driver	3 mo	None	Blood + (Br) abortus (3 x)	1 to 1.250	All normal	(Granulomas in lobules)
7	61	M	Farmer	1 yr	Left hemiplegia (cause unknown)	Blood + (Br) abortus (3 x)	1 to 410	All normal	Moderate fatty metamorphosis with focal mononuclear cells granulomas
8	56	F	Farmer's wife	3 yr	Spontaneous abortion of spine of T <sub>6</sub> with paravertebral abscess	Blood + (Br) abortus from blood (2 x)	1 to 1.80	Thymol turbidity 9 units urine urobilinogen 5 units in 2 hr cephalin cholesterol 2+ and 3+ urine coproporphyrin 11 $\mu$ units per 24 hr	Granulomas in lobules
9	32	M	Busine's	3 wk	None	Blood - (culture sterile)	1 to 5120	All normal	(Granulomas in lobules)
10	25	M	Meat packing plant employee	6 mo	Committed suicide	Blood - (culture sterile)	1 to 1.0	Thymol turbidity 7 units cephalin cholesterol flocculation 2+ 7+	(Granulomas in lobules and in portal spaces Evidence of healing)
11	30	M	Farmer	5 mo	None	Blood - (culture sterile)	1 to 200	All normal	Moderately severe mononuclear infiltrate of portal spaces Granulomas in lobules

## Liver function tests employed routinely included

1 Serum bilirubin (Ducci and Watson J Lab &amp; Clin Med 30 393 191)

Thymol turbidity (MacLagan Brit J Exper Path 3: 34 1941)

3 Cephalin cholesterol (Hanger J Clin Investigation 18 61 1939)

4 Sulfabromothaleim (Mateer et al J A M A 11 1913)

5 Quantitative urine urobilinogen (Watson Am J Clin Path 6 4 8 1936)

Am J Clin Path 14 605 1944 and 17 108 1947)

6 Urinary coproporphyrin (Schwartz et al J Biol Chem 163 133 1947)

and/or quantitative urine Ehrlich reaction (Watson et al

cells with pink cytoplasm and indented vesicular nuclei as seen in Fig 1. There was one Langhans' type of giant cell with peripherally situated nuclei. Necrosis was absent and reticulum fibers were demonstrated with Wilder's silver stain both peripherally and centrally. No organisms could be demonstrated with Verhoeff's carbolfuchsin and MacCallum's modification of Goodpasture's stain.

Fig 1.—Photomicrograph ( $\times 175$ ) liver biopsy secured at time of splenectomy in Case 1. The granulomatous lesion consists of a central collection of epithelioid cells and a peripheral zone of small lymphocytes.

CASE 2—L. N., a 29 year old farmer, had been ill over a period of eleven months with weakness, chills, fever and nocturnal sweats. Six months after the onset, a blood culture showed the presence of *Br abortus*, and a course of therapy with sulfadiazine resulted in only temporary improvement. Five months later *Br abortus* was again recovered from a blood culture. Except for enlarged lymph nodes, there were no physical abnormalities. The liver and spleen were not enlarged. Laboratory studies showed a leucocyte count of 6,900 with 56 per cent polymorphonuclear leucocytes, 33 per cent lymphocytes, 8 per cent monocytes, and 3 per cent eosinophiles. The erythrocyte sedimentation rate was 28 mm in one hour (Westergren). The agglutinin titer for *Brucella* was 1 to 2,560. Liver function studies revealed an excretion of urobilinogen and coproporphyrin in the urine just slightly above the normal range.

Peritonoscopy was performed. The surfaces of the liver appeared normal, and a biopsy of the liver was secured with the aid of a modified Silverman needle.<sup>8</sup>

**Study of Liver Biopsy.** The biopsy specimens included a slender fragment measuring 10 by  $1\frac{1}{2}$  millimeters. Microscopically there was a normal architectural pattern. Some of the portal spaces contained a few round cells, which

were also present in small numbers in the sinusoids and in focal collections among the hepatic cells. The azocarmine stain failed to demonstrate any appreciable increase in connective tissue. The liver cells contained a small amount of finely divided golden brown pigment, part of which stained for iron. In several sections, granulomas with epithelioid cells were noted, the two smallest being in the central portion of a liver lobule and the three larger occupying portal

FIG. —Photomicrograph ( $\times 100$ ). Needle biopsy of the liver from Case 2 secured at the time of peritoneo copy. An epithelioid cell granuloma containing Langhans' type giant cells is present in a portal space.

spaces. The smallest lesion consisted of about six epithelioid cells surrounded by approximately a dozen small lymphocytes. The largest occupied the better portion of a small portal space, and showed a peripheral zone of lymphocytes and central epithelioid cell zone as seen in Fig. 2. The cell outlines were indistinct, the cytoplasm having fused, forming syncytial masses resembling Langhans' type giant cells. The nuclei were vesicular, many being indented. Necrosis was absent and reticulum fibers were demonstrated between the epithelioid cells. No organisms were found with acid fast and Gram's stains.

CASE 3—A. M. S., a 47 year old, white, male confectioner became ill one month before entry with fever, drenching night sweats, migratory arthralgia, severe headaches, insomnia, and a marked tremor of his hands. He was a moderately severe alcoholic. His acute illness was contracted through ingesting raw milk and cream obtained from a herd of cattle with Bang's disease. The abnormal physical findings included a tender liver that was felt 4 cm. below the right costal margin. Laboratory data revealed a leucocyte count of 4,100, and a differential count of 49 per cent polymorphonuclear neutrophils, 39 per cent lymphocytes, 5 per cent eosinophiles, 6 per cent monocytes and 1 per cent basophiles. The erythrocyte sedimentation rate was 68 mm. in one hour (Westergren). *Brucella agglutinins* were present in the serum in a titer of 1 to 5120 and *Fr. abortus* was cultured from the blood. Liver function studies showed abnormal excretion of urinary pigments and 21 per cent retention of sulfabromthalein (Table I).

The patient was treated with streptomycin in doses of 0.4 Gm every three hours, but because of the appearance of purpura and an accentuation of the fever, therapy was discontinued. He then received sulfadiazine, and coincident with this improvement in his condition was noted. Although the patient felt better and returned to work, three months after leaving the hospital *B. abortus* was recovered from his blood. After a lapse of another three months, cultures of blood remained sterile.

During the patient's initial stay in the hospital Dr. Richard Varco secured a biopsy under local anesthesia of the left lobe of the liver through a small midline abdominal incision. Gross inspection and palpation of the small area of the liver that presented itself in the incision revealed no apparent abnormality. A portion of the biopsied specimen was cultured for Brucella; it proved to be sterile.

Fig. 3—Photomicrograph (X75) of liver biopsy from Case 3. A confluent granuloma is present as described in the text. In addition there is evidence of a patchy fatty metamorphosis.

*Study of Liver Biopsy* The specimen examined histologically was a fragment from the liver edge measuring 4 by 4 by 3 millimeters. Microscopically, there was a patchy, fatty metamorphosis and a moderately severe, round cell infiltration in the portal spaces. A large epithelioid cell granuloma was present, covering an area slightly greater than a high-power field. Its location with respect to the liver lobule was uncertain, but it did not appear to be within a portal space. It consisted of epithelioid cells, lymphocytes, and a few plasma cells arranged in smaller rounded groups suggesting that it was made up of several smaller confluent granulomas (Fig. 3). In step sections, on which bacterial and other special stains were carried out, the granuloma disappeared and only two small lesions of a similar nature could be found. These consisted of a collection of four or five epithelioid cells surrounded by a dozen or more lymphocytes. No definite bacteria were demonstrated, and there did not appear to be an increase in connective tissue in the portal spaces.

CASE 4—E S, a 55 year old housewife had been ill for twenty two months before she was first seen at the University Hospitals. She had experienced marked fatigue for one year before fever and arthralgia appeared. During the time that he was ill a number of cows on her farm were found to have Bang's disease. Physical examination revealed an individual who appeared chronically ill, he complained of severe headaches and painful joint pain over the lumbar area was aggravated by movement of the legs. The interphalangeal joints of both hands were enlarged and motion was limited. The edge of the liver was just palpable at the costal margin. The leucocyte count was 7500 with 61 per cent polymorphonuclear

Fig. 4—Photomicrograph ( $\times 35$ ) of liver biopsy secured in Case 4. An epithelioid cell granuloma containing a giant cell is shown.

neutrophils 35 per cent lymphocytes 3 per cent eosinophiles, and 1 per cent basophiles. The erythrocyte sedimentation rate was 30 mm in one hour. Agglutinins for *Brucella* were present in a titer of 1 to 640. Repeated cultures of blood remained sterile. The only abnormal liver function was a slightly elevated serum bilirubin. She improved while in the hospital but since that time there has been no opportunity to follow her progress.

A biopsy of the liver was obtained through a short midline abdominal incision by Dr K. A. Merendino. The visible surface of the liver appeared normal. A portion of the biopsy cultured for *Brucella* remained sterile.

*Study of Liver Biopsy.* A specimen measuring 1 by 5 by 5 cm, from the liver edge was blocked and sectioned. Microscopically the general architecture was normal. Some of the portal spaces, particularly the smaller ones, contained a prominent lymphocyte and plasma cell infiltrate. No increase in fibrous tissue could be demonstrated. Occasional necrotic liver cells were present, surrounded by mononuclear leucocytes as well as a number of the so called regenerative forms with large hyperchromatic nuclei. Many hepatic cells contained a small

Approximately ten epithelioid cell granulomas were noted chiefly within lobules, one being in a portal space. Fig. 4 is a photomicrograph of this biopsy. The largest of these granulomas occupied one half the area of a high-power field, the others being much smaller. They consisted of collections of epithelioid cells with vesicular, indented nuclei surrounded by small lymphocytes. Necrosis was absent and reticulum fibers were demonstrated within the lesions. No organisms were seen in preparations appropriately stained.

**CASE 5**—M. M., a 66-year-old housewife, had pain in the left lower quadrant, in addition to fatigability, night sweats, and weight loss. Her illness had extended over a period of six months. Physical examination revealed a febrile patient having a palpable spleen but the liver was not palpable. The leucocyte count was 3,850 with 51 per cent polymorphonuclear neutrophils, 48 per cent lymphocytes and 1 per cent monocytes. The erythrocyte sedimentation rate was 30 mm. in one hour. The agglutinin titer in her blood for *Brucella* was 1 to 640, and *Br. abortus* was obtained from a culture of blood. Liver function studies revealed an abnormal thymol turbidity test and the urinary coproporphyrin value was elevated.

A peritoneoscopic examination was attempted. The surface of the liver appeared normal, but a satisfactory biopsy was not obtained. Therefore Dr. K. A. Merendino secured a biopsy through a midline abdominal incision under local anesthesia. Part of the specimen was cultured for *Br. abortus* without success.

**Study of Liver Biopsy** The biopsy specimen measured 8 by 4 by 3 mm. and was of normal appearance. Microscopically there was some distortion of the architecture with a suggestion of increased connective tissue and patchy areas of vacuolated liver cells. Many portal areas showed dense lymphocytic infiltration. Throughout there were scattered necrotic liver cells surrounded by mononuclear leucocytes. A few liver cells contained fine brown pigment which did not stain for iron. In step sections, approximately six epithelioid cell granulomas were present at each level. These were of small size consisting of central collections of epithelioid cells varying from five to twenty in number surrounded by a zone of small lymphocytes and occasional plasma cells. A granuloma is shown in Fig. 5. Necrosis was absent and reticulum fibers were demonstrated between the epithelioid cells. No organisms were found in appropriately stained preparations.

Fig 5—Photomicrograph (X3) Case 7. One of several granulomas is shown. The surrounding liver cells contain fat vacuoles.

Fig 6—Photomicrograph (X50) Case 5. The second biopsy was taken six months following the first. Three small granulomas are shown in a single field. The peripheral lymphocytic zone and central epithelioid cells are demonstrated.

liver appeared smooth. A piece of the tissue failed to yield *Brucella* after culturing for the organisms.

The patient was subsequently discharged from the hospital. It was remarkable that the patient experienced so few symptoms in view of the positive bacteriologic studies.

*Study of Second Liver Biopsy* The biopsy specimen measured 10 by 8 by 5 millimeters. Microscopically, the general liver architecture remained unchanged. There was some diminution in the amount of fat present but more necrotic liver cells could be found than in the previous biopsy. In some instances, two to six necrotic liver cells were noted surrounded by mononuclear leucocytes and an occasional polymorphonuclear leucocyte. A transition from these focal necroses to small granulomas was noted. There appeared to be about the same number of granulomas as was noted previously (Fig 6). In one portal space a rounded scar containing small lymphocytes suggested a healed granuloma. Bacterial stains were negative.

Fig 7—Photomicrograph ( $\times 225$ ). Case 6. One of the granulomas is shown located adjacent to the wall of a central vein.

CASE 6—J. J., a 41-year-old truck driver, had been ill for three months with easy fatigability and lack of energy, succeeded by chills, fever, and night sweats. Four months before the onset of his illness he had worked in a meat packing plant for six months. There were no abnormal findings on physical examination. The laboratory results included a leucocyte count of 4,500 with 40 per cent polymorphonuclear neutrophils and 60 per cent lymphocytes. The erythrocyte sedimentation rate was 77 mm in one hour (Westergren). The agglutinin titer for *Brucella* was 1 to 640, and *Br. abortus* was obtained from a culture of blood. He was treated with sulfadiazine and felt improved. Seven weeks later he was readmitted to the hospital because of chills, fever, malaise, headache, and a nonproductive cough. His temperature was 103.3° F, and the liver and spleen were now palpable. Cultures of blood yielded *Br. abortus*. Liver function studies were within normal limits. A biopsy of

the right lobe of the liver was made with the Silverman needle. He was treated with sulfadiazine again, but because of the appearance of a granulopenia, therapy with this drug was discontinued, and streptomycin was administered. Because of the appearance of a skin eruption, and an accentuation of his fever, treatment with streptomycin was omitted. He finally approached a normal state of health and left the hospital.

*Study of Liver Biopsy* The strip of tissue obtained revealed a fairly normal liver architecture without an increase of connective tissue. The portal spaces contained a moderate mononuclear infiltrate. Scattered liver cells contained fat vacuoles. In all, nine epithelioid cell granulomas were noted which were of varying size, the largest occupying most of a high power field. This is shown in Fig. 7. It was located adjacent to a central vein and consisted of a compact collection of epithelioid cells interspersed with small lymphocytes. Two Langhans type giant cells were present in the center. There was no necrosis. The smallest of the lesions consisted of four or five epithelioid cells forming a rounded mass within a sinusoid.

CASE 7—G. W., a 61 year old farmer, presented a vague history of epigastric distress, recent left hemiplegia, loss of strength, reduction in weight and night sweats. A diagnosis of peptic ulcer had been made in the past. There was no definite evidence of hypertension. In assembling further clinical data it was learned that a herd of cattle owned by the patient had Bang's disease and abortions were occurring. The physical examination was essentially normal except for increased reflexes of the left upper and lower extremities and a liver that was palpable at the costal margin. Laboratory data showed a leucocyte count of 7,450 with 50 per cent polymorphonuclear neutrophils, 39 per cent lymphocytes and 11 per cent monocytes. A lumbar puncture revealed normal findings. The erythrocyte sedimentation rate was 29 mm in one hour (Westergren). Brucella agglutinins were present in the blood in a titer of 1 to 640, and cultures of blood yielded *Br. abortus*. Liver function studies revealed normal values.

A liver biopsy was carried out with a modified Silverman needle. The patient was treated with a combination of streptomycin and sulfadiazine for two weeks. His response was satisfactory and he left the hospital improved.

*Study of Liver Biopsy* A strip of hepatic tissue showed a mild fatty metamorphosis with frequent focal collections of mononuclear cells and scattered polymorphonuclear leucocytes. Present in these foci were a few epithelioid cells, and in others there were discrete round granulomas composed mainly of epithelioid cells with an occasional Langhans type of giant cell, as illustrated in Fig. 8.

CASE 8—K. S., a 56 year old, white farm wife, became ill three years before admission with a bilateral pleuritic pain, fever, night sweats, and pain over the lower part of the spine. In the intervening time she had lost 70 pounds in weight. Two years after the onset she had vaginal bleeding of one month's duration, the cause of which was not ascertained. This was accompanied by a urinary tract infection which responded well to treatment with penicillin. Shortly thereafter, the patient had a cholecystectomy following an acute episode of right upper quadrant colic, vomiting and chills. About nine months later, she was considerably debilitated and was admitted to a tuberculosis sanatorium with a diagnosis of Pott's disease of the spine. Tuberculosis was excluded as a cause of her illness and a diagnosis of active brucellosis with spondylitis was considered. She was admitted to the University Hospitals for treatment. The source of the patient's infection could not be ascertained although she drank raw milk. On examination she appeared poorly nourished and chronically ill. The spleen was palpable 4 cm. below the costal margin, and the liver, 6 cm. below the costal

Fig 8—Photomicrograph (X400) Case 7 A small granuloma is present

Fig 9—Photomicrograph (X270) Case 8 A small granuloma is present within a portal space.

margin. There was tenderness to percussion extending from the lower thoracic level down to the lumbar area. Laboratory data revealed a leucocyte count of 3,900 with 15 per cent neutrophils, 41 per cent lymphocytes, 7 per cent monocytes, 1 per cent eosinophiles and 1 per cent basophiles. The erythrocyte sedimentation rate was 46 mm in one hour (Westergren). Agglutinins for *Brucella* were present in the blood serum in a titer of 1 to 1:50. *Pr. abortus* was identified in blood cultures on two occasions. Roentgenologic examination of the thoracic spine revealed an inflammatory process involving the seventh and eighth thoracic vertebrae, associated with destruction of the intervertebral disc and a perivertebral mass. Liver function studies showed abnormal findings as given in Table I.

Fig. 10—Photomicrograph ( $\times 400$ ) Case 9. A small granuloma of moderate size is shown.

A liver biopsy was carried out at the bedside with a modified Silverman needle. The patient was treated with a combination of streptomycin and sulfadiazine, receiving 0.5 Gm. of the former every six hours for two weeks, and 1 Gm. of sulfadiazine every four hours for a similar period. She improved remarkably in this period, and left the hospital. A checkup one month later showed her to be afebrile and abacteremic, and feeling greatly improved.

**Study of Liver Biopsy.** The specimen measured 2 cm. in length and 1 mm. in diameter. There was an extensive mononuclear infiltrate of the portal areas, but there was no increase in connective tissue. Scattered throughout both portal areas and within liver lobules were granulomas of varying size, the largest of these approximating the measurements of a portal area. Fig. 9 shows a small granuloma within a portal space. The lesions were formed by epithelioid cells surrounded by varying numbers of lymphocytes. Central necrosis was absent. The liver cells contained some fine brown pigment and scattered regenerative and degenerative forms were present.

**CASE 9**—A 32-year-old businessman had the onset of fever and sweats about three weeks before entry to the hospital. Sulfonamide and later penicillin were given without coincident improvement. There were no abnormal findings on physical examination. Data from laboratory procedures showed a leucocyte count of 8,300 with 56 per cent polymorphonuclear

neutrophils, 30 per cent lymphocytes, and 7 per cent eosinophils. The erythrocyte sedimentation rate was 44 mm in one hour (Westergren). Agglutinins for *Brucella* were present in a titer of 1 to 5,120, but repeated cultures of blood remained sterile. Liver function studies showed normal values.

A biopsy of the liver was performed with a modified Silverman needle. A portion of the tissue was cultured unsuccessfully for *Brucella*. The patient was treated with a combination of streptomycin and sulfadiazine over a period of two weeks. He felt considerably improved on discharge from the hospital. One month later he was afebrile and had no bacteremia.

Fig. 11—Photomicrograph ( $\times 150$ ) Case 10 showing a large granuloma in liver studied post mortem

**Study of Liver Biopsy** A strip of liver showed a moderate fatty metamorphosis. There was a heavy lymphocytic infiltrate in the portal areas. Well-formed epithelioid tubercles were present, one of which filled almost the entire high-power field in the portal space. This lesion consisted of a central collection of epithelioid cells and a peripheral zone comprising lymphocytes and plasma cells without necrosis. Fig. 10 shows a granuloma.

**CASE 10**—R. B., a 25-year-old meat packing plant employee, had been ill for six months complaining of chills, sensations of fever, and night sweats. He was quite nervous. On examination the outstanding feature was a firm spleen palpated 6 cm below the costal margin. Laboratory information included a leucocyte count of 4,700 with 43 per cent polymorphonuclear neutrophils, and 53 per cent lymphocytes. The sedimentation rate of the erythrocytes was 60 mm in one hour (Westergren). Agglutinins for *Brucella* were present in the blood in a titer of 1 to 5,120. Blood cultures remained sterile. Liver function studies performed five months before the liver was studied histologically revealed abnormal values as shown in Table I.

The patient was not treated specifically, but he abstained from work and rested. He appeared to be getting along fairly well, when he took his life by hanging. A complete post mortem study was carried out by Dr. Robert Hebbel and the only significant histologic findings related to the liver.

*Study of Liver (Post Mortem)* The liver weighed 1 850 grams. Its capsule was smooth. The markings on sectioning the organ were normal. The gall bladder contained greenish bile. The wall appeared normal and the extrahepatic bile ducts were patent and unchanged. Microscopic examination showed the presence of scattered granulomas in the liver. The largest occupied the greater part of a high power field. They were round to oval, located within portal areas and within liver lobules. Fig. 11 shows a granuloma beneath the capsule.

Fig. 11—Photomicrograph ( $\times 100$ ) Case 11 showing a small granuloma

There was a predominance of small lymphocytes and plasma cells with a lesser number of epithelioid cells grouped centrally. No giant cells were noted and necrosis was absent. The smaller lesions consisted of dense collections of lymphocytes and plasma cells. It is of interest that several of these larger foci showed evidence of healing consisting of a diminution of cellularity with an increase in collagen fibers.

CASE 11—H S, a 35 year old white farmer had been ill for five months. The onset was marked by severe chills, fever, malaise, anorexia, and weakness. During the course of his illness he had lost 49 pounds in weight. Night sweats had been prominent. The patient was severely exposed to Bang's disease existing in a herd of cattle. He had removed a retained placenta with his unprotected hands. He had also ingested raw milk from this herd. It is of interest that three years previously he had had hepatitis of unknown etiology. There were no physical abnormalities apparent on physical examination except for generalized lymphadenopathy and a skin eruption consistent with erythema multiforme. Laboratory data showed a leucocyte count of 6000 with 52 per cent polymorphonuclear neutrophils, 39 per cent lymphocytes, 4 per cent eosinophiles, 4 per cent monocytes and 1 per cent basophiles. *Brucella* agglutinins were present in his blood in a titer of 1 to 640. Repeated cultures of venous blood remained sterile. Liver function studies were all within normal limits.

A liver biopsy was obtained at the time of peritoneoscopy. The surfaces of the liver appeared normal. The patient was treated with streptomycin and sulfadiazine for a period of two weeks. He improved markedly and has felt well since leaving the hospital.

*Study of Liver Biopsy* There were two thin fragments of liver measuring 1 and 2 cm in length and 1 mm in diameter. The portal area showed a moderately severe infiltrate with mononuclear cells. Fig 12 shows a small granuloma. Within several liver lobules there were small granulomas consisting of central epithelioid cells and a surrounding zone of lymphocytes.

#### DISCUSSION

An outstanding feature in this study of eleven patients is that hepatic lesions have been present in every instance. The presence of granulomas in the liver lobule or in the portal areas, with a portal cellular infiltrate in several cases indicates that these hepatic lesions cannot be considered as complications but as a part of the natural course of the disease. The presence of the hepatic lesion has no relationship to the severity of the infection or to the clinical status of the patient. The changes have been observed in individuals who were quite ill, and in others who were symptomatically well at the time the biopsy was made.

The genesis of these lesions is worthy of comment. Thus far, in the human investigations, the hepatic changes have been associated only with *Br. abortus*. This species is usually less invasive than *Brucella suis* or *Brucella melitensis*. The appearance of epithelioid cells in the liver lobules, and in the portal spaces, undoubtedly represents a response to the invasion of cells by *Br. abortus*. This infiltration with epithelioid cells indicates either an efficient defense mechanism or invasion of the tissue by microorganisms of low virulence. From observations being conducted in this laboratory by Dr. A. I. Braude in experimentally infected animals,<sup>9</sup> it appears that a combination of these factors is responsible for the noncaseating granuloma. He has observed severe caseation occurring with *Br. suis* and *Br. melitensis*. He has also observed that just a few days before the appearance of epithelioid cells there is an intracytoplasmic invasion of the hepatic cells by demonstrable *Brucella*, but without any surrounding cellular reaction. In the present investigations, attempts were made to culture a portion of the hepatic tissue containing granulomas obtained from four patients, and in each instance the cultures remained sterile.

The hepatic lesions that have been described in this report are not specific for brucellosis. The granulomas in the bone marrow of patients having brucellosis could not be distinguished from sarcoidosis, as pointed out elsewhere.<sup>1</sup> This also applies to the hepatic granulomas and sarcoidosis. Obviously, the histologic diagnosis of involvement of the liver in sarcoidosis should not be made until brucellosis has been carefully ruled out. In addition, the granuloma of brucellosis cannot be differentiated from that observed in some cases of tuberculosis and syphilis.

The simultaneous performance of a battery of liver function tests and an hepatic biopsy has shown little or no hepatic dysfunction in several of the patients having demonstrable changes in the tissues. Instances of hepatitis, a diagnosis based upon clinical and biochemical evidence of liver dysfunction, have been described in patients with brucellosis.<sup>10, 11</sup> A question which this study has provoked is whether brucellosis will cause extensive and permanent

hepatic changes such as cirrhosis of the liver. This aspect of the problem will be considered in another paper. Individual instances of cirrhosis occurring in brucellosis have been reported in this country.<sup>1, 13, 14</sup> Frequent reference to this association has been made from time to time in the continental literature.<sup>1, 4</sup> In this laboratory, it has not been possible thus far to produce cirrhosis of the liver in experimentally infected animals. While a direct relationship between hepatic cirrhosis and human brucellosis has not been clearly established there is accumulating evidence that brucellosis may be a major accessory agent in the genesis of severe and, at times, fatal cirrhosis.

The accurate diagnosis of brucellosis is dependent upon laboratory tests including cultural and serologic methods. Too frequently bacteriologic evidence for brucellosis is lacking, and the remaining data may be inconclusive, or even conflicting. Therefore any procedure that will aid in the diagnosis of active brucellosis will be looked upon favorably by clinicians. The present studies indicate that demonstrable histologic changes may be present in the livers of at least the majority of patients having active brucellosis. The removal of an adequate specimen of liver by means of a needle biopsy may be a useful diagnostic procedure in the more doubtful cases. Although more satisfactory treatment is now available for brucellosis in the form of combined treatment with streptomycin and sulfadiazine one does not like to submit doubtful cases to such therapy because of the expense entailed and also because of the potential toxic reactions either of the two drugs may induce.

#### SUMMARY

1 Biopsies of the liver have been carried out in ten patients with active brucellosis. The histologic appearance of tissue obtained post mortem has been described for an eleventh case. A battery of liver function tests was carried out simultaneously with the biopsies in ten cases.

2 The basic hepatic lesions are granulomas in the lobules and portal spaces along with a cellular infiltrate in the portal areas. The granuloma is not specific for brucellosis and cannot be distinguished from sarcoidosis, and, in some instances from the lesions of tuberculosis and syphilis.

3 In several instances there was little or no deviation from normal in the liver function tests, although definite histologic changes were apparent. While a direct relationship between brucellosis and cirrhosis of the liver has not been established, there is accumulating evidence that brucellosis may play an important accessory role in the genesis of cirrhosis.

4 It is suggested that biopsy of the liver may be employed for diagnostic purposes in doubtful cases of human brucellosis.

# THE TREATMENT OF PNEUMOCOCCAL PNEUMONIA BY PENICILLIN IN AQUEOUS SOLUTION AT LONG INTERVALS

EFFECTIVENESS OF TWO DOSES IN FIRST TWENTY-FOUR HOURS FOLLOWED BY  
SINGLE DAILY INJECTIONS

MORTON HAMBURGER, M.D. JEROME R. BERMAN, M.D.  
ROBERT T. THOMSON, M.D. AND M. A. BINKSHORN, M.D.  
CINCINNATI, OHIO

THE technique of administering penicillin has been the subject of considerable investigation since the original discovery that the tubules of the kidney eliminate penicillin rapidly from the blood. Thus many attempts have been made to develop preparations which would either permit penicillin to be absorbed slowly from a depot into which it was injected or which would retard its excretion from the body.<sup>1-3</sup> These efforts were based upon the assumption that constant "therapeutic" blood levels are necessary for the successful treatment of most infections. In the early experience of Tillet,<sup>4</sup> however, and also more recently, evidence has been presented which casts doubt upon the necessity for continuous blood levels in all situations.<sup>5-10</sup>

An opportunity to subject these considerations to clinical trial existed in the Cincinnati General Hospital, where many patients with pneumococcal pneumonia are treated and where typing of pneumococci is still carried out. During the winter of 1947-1948 therefore the efficacy of one or two daily doses of crystalline penicillin G in distilled water was investigated in a series of 118 cases of pneumonia, sixty-four of which were caused by demonstrated typed pneumococci. It is the purpose of this communication to describe the results of this regimen, which has been associated with a lower mortality rate for pneumonia than has ever been observed in this hospital.

*Plan of study*—Beginning Dec. 1, 1947, all patients admitted to the Medical Service of the Cincinnati General Hospital with a primary diagnosis of pneumonia were treated with penicillin but no other chemotherapeutic agents. The only exceptions were cases where meningitis or endocarditis complicated pneumonia and where the pneumonia was believed to be caused by gram-negative bacilli. Streptomycin and sulfonamides were administered in addition to penicillin when gram-negative bacilli were believed to be the cause of the pneumonia. Such cases are not included in the present series.

Before penicillin was administered, a sample of sputum was cultured in blood broth for typing of pneumococci, and a blood culture was made. The latter consisted of 3 c.c. of blood added to 50 c.c. infusion broth in a flask, and an agar pour plate prepared from 1 c.c. of the patient's blood. An x-ray of the chest was made in every case within twenty-four hours of admission, and follow-up films were made in most cases.

Three dosage schedules were investigated (Table I). At the beginning of the study patients admitted on the odd days of the month, i.e. the 1st, 3rd, 5th, etc. were given 300,000 units of crystalline penicillin G in 3 c.c. distilled water intramuscularly as soon as the diagnosis of pneumonia was made and the material for blood and sputum cultures secured. This

This investigation was supported by grants from Merck & Co., Inc., Rahway, N. J. and the United States Public Health Service Antibiotic Study Section of the Division of Research Grants and Fellowships, National Institute of Health.

Received for publication Aug. 17, 1948

TABLE I INTRAMUSCULAR PENICILLIN DOSAGE SCHEDULES INVESTIGATED IN THIS STUDY

NAME OF SCHEDULE	DOSAGE	WHEN USED
300,000 series	300,000 units crystalline penicillin G in 3 c.c. distilled water on admission, and every 24 hours for 6 days or until temperature is normal for 48 hours, 1 "booster" dose" given 12 hours after first dose only	Odd days of month, Dec 15, 1947, to June 1, 1948
200,000 series	Same as 300,000 series, except that each dose consisted of 200,000 units in 2 c.c. distilled water	Even days of month, Feb 21, 1948, to June 1, 1948
25,000 q 3 h series	25,000 units crystalline penicillin G in saline or distilled water every 3 hours for 6 days or until temperature was normal for 48 hours	Even days of months, Dec 15, 1947, to Feb 20, 1948

dose was repeated every twenty four hours for six days or until the temperature was normal for forty eight hours. In addition to the daily dose, a "booster" dose of 300,000 units in distilled water was given twelve hours after the initial dose, *on the first day only*. This schedule, which will be referred to as the "300,000 series," was continued throughout the entire period of the investigation, from Dec 15, 1947, to June 1, 1948.

Patients admitted on the even days of the month were given penicillin according to the accepted conventional method, i.e., 25,000 units in saline or distilled water every three hours, for six days or until the temperature was normal for forty eight hours. This schedule was adhered to from Dec 15, 1947, until Feb 20, 1948. At that time it was apparent that clinical results with the two schedules were indistinguishable. It seemed advisable to determine, therefore, whether 200,000 units might be as efficacious as 300,000 as the basic dosage in the "one a day" treatment. The 25,000 units every three hours program was, therefore, terminated, and in its place was substituted a schedule identical with that employed on the odd days of the month, except that 200,000 units crystalline penicillin G in 2 c.c. distilled water were used instead of 300,000 units. This schedule, which will be referred to as the "200,000 series," was followed from Feb 20, 1948, through June 1, 1948.

#### ANALYSIS OF THE CASE MATERIAL

*Distribution According to Type*—Pneumococci were recovered from the sputum of sixty-four of the 118 cases in the 200,000 and 300,000 series. Tabulation of the type distribution (Table II) showed that the commonest types were, in order 2, 7, 4, 3, 14, 1, 5, 9, and 18.

The cases from which no pneumococci were recovered included an assortment of pulmonary conditions, and have not been analyzed in detail. Most of them presented the clinical picture of pneumococcal pneumonia, some more closely resembled "virus pneumonia", and a few were cases of acute infections superimposed upon chronic lung disease such as bronchiectasis. Though they cannot properly be included in mortality statistics for pneumococcal pneumonia, they are worth presenting at this time because the patients were all acutely and at least moderately ill, as patients must be to gain entrance to the wards of the Cincinnati General Hospital.

*Bacteremia*—Twenty of the sixty-four pneumococcal cases had positive blood cultures, an incidence of 31.2 per cent. The distribution of bacteremia among the 200,000 and 300,000 series is presented in Table III.

## RESULTS OF TREATMENT

The results of treatment in the sixty-four pneumococcal cases are summarized in Table VII. There were four deaths, a mortality of 6.3 per cent. When the bacteremic cases were calculated separately from the nonbacteremic, we found a mortality rate of 15 per cent for the former and 2.3 per cent for the latter. In the small series of cases treated with 200,000 units at a time, the mortality was almost the same as in the 300,000 series.

Total	44	1	2.3	20	3	15.0	64	4	6.3

The clinical response with both dosage schedules was rapid in most cases and dramatic in some. Often by twelve and usually by the end of twenty-four hours after the first dose the temperature had dropped precipitately and the patient experienced great subjective improvement. This was more striking in the younger than in the older patients.

Resolution of the pneumonic lesion as shown on roentgenograms was not noticeably different from that experienced with other forms of treatment used in recent years. The lungs of most patients cleared within about a week, though in some instances progress was slower. Representative films are presented in Figs. 1 and 2. Complications were conspicuously absent. Once treatment had been inaugurated meningitis, endocarditis, arthritis, or empyema did not

Fig 1—Bacterial Type 3 pneumococcal pneumonia in a 3 year old woman treated on the 300 000 unit schedule

ensue In two instances sterile pleural effusions appeared after recovery from the pneumonia, and in neither case did the effusion recur after its removal by thoracentesis

Three of the four deaths occurred in patients in the eighth decade The four fatal cases are summarized below

1 E G, CGH233031 This 79 year-old woman was admitted with the history of an acute febrile respiratory illness of a week's duration and chronic cough of several years' duration The temperature was 101.8° F, pulse 120, respirations 48, and blood pressure 180 systolic and 90 diastolic She was very ill, presenting signs of consolidation over the right upper lobe and evidence of patchy pneumonia in all other lobes In addition she suffered from decompensated arteriosclerotic heart disease

Sputum culture yielded pneumococcus Type 34, blood culture was negative Admission white blood count was 8,800

She was placed on the 300,000 unit penicillin schedule, given oxygen, and digitalized She responded with temporary improvement, but lost ground and died six days after admission Autopsy revealed evidence of chronic bronchiectasis and pulmonary fibrosis, bilateral lobular pneumonia, pulmonary edema, and hypertrophy of the right ventricle of the heart

2 T O'B, CGH235314 This 77-year-old white man was admitted to the hospital on Feb 20, 1948, in a critical state and died eight days later He had been ill for about three weeks, though no specific symptoms could date the onset of the pneumonia Temperature 100, pulse 90, respirations 22, blood pressure 130 systolic and 60 diastolic He was severely dehydrated and greatly undernourished Cyanosis was moderate There were signs of pneumonia in the right upper lobe, evidence of generalized arteriosclerosis and auricular fibrillation

Both sputum and blood cultures yielded Type 2 pneumococcus The white blood count was 6,000, the blood urea nitrogen 40 milligrams per cent

He was placed on the 300,000 unit schedule, and though blood and sputum cultures were negative on the third hospital day, he failed to improve clinically It seemed remarkable that he lived eight days

An autopsy revealed confluent lobular pneumonia involving the right upper, middle and lower lobes There was aspirated food in the left lower lobe with partial occlusion of the bronchus There was no meningitis or endocarditis

3 L V, CGH236791 This was a case of fulminating Type 2 pneumococcal pneumonia in a woman of 34 The patient was admitted to the hospital on April 1, 1948, with pneumonia of about three days' duration Temperature 102° F pulse 120, respirations 28, blood pressure 106 systolic and 40 diastolic There were signs of consolidation in the right lower and middle lobes On her way to the ward, she went into shock She was placed on the 300,000 unit schedule and given 500 cc plasma and 2,000 cc 5 per cent glucose intravenously but died twelve hours later Permission for autopsy was denied

Cultures of sputum and blood yielded Type 2 pneumococcus The white cell count was 7,250 The blood urea nitrogen was 12 milligrams per cent

*A. I. B., CCH237555* This 74-year-old white man was admitted to the hospital on April 26, 1948, and died six hours later. The temperature was 101.4° F, pulse 120, respirations 28, and blood pressure 140 systolic and 90 diastolic. He presented the signs of decompensated atherosclerotic heart disease and pneumonia of the left lower lobe. He had been acutely ill for two weeks and received an unknown amount of sulfadiazine and penicillin before admission to the hospital.

Blood and sputum cultures yielded Type 15 pneumococcus. The white blood count was 32,350.

While on the ward he received one injection of 200,000 units of penicillin. Permission for autopsy was not obtained.

Only one death occurred among the fifteen cases of pneumococcal pneumonia treated with 25,000 units penicillin every three hours. This patient was a 94-year-old man suffering from Type 1 pneumococcus pneumonia who died on the eighth day of treatment. The only bacteremic patient in this series recovered. The mortality rate was 3.4 per cent.

There were no deaths among the fifty-four cases which were diagnosed as "pneumonia, but from which no pneumococci were recovered. Since several series of cases of "pneumonia have been reported in the literature in which pneumococcus typing was not carried out, we have calculated the over-all mortality in our 118 cases of pneumococcal and nonpneumococcal pneumonia treated with 200,000 or 300,000 units a day for comparison with such series. The rate was 3.4 per cent.

#### DISCUSSION

The clinical results reported in this paper are of interest from the practical and theoretical points of view. In this time of shortage of nursing and other hospital personnel the advantages of administering penicillin only twice the first day and once a day thereafter are evident. There are also advantages in the use of crystalline penicillin free of procaine, beeswax, and oils of various types which though they have served us well do produce a certain number of undesirable side reactions.

The mortality rates—15 per cent in bacteremic, 2.3 per cent in nonbacteremic, and 6.3 per cent for bacteremic and nonbacteremic patients—are lower than have been encountered previously in the Cincinnati General Hospital for similar series of cases. Thus, in the years 1945-1946 and 1946-1947 the gross mortality in pneumococcal pneumonia was, respectively, 12.0 per cent and 14.6 per cent. The patients in these series were unselected. There was no exclusion because of age, state of sobriety, severity of illness, or duration of pneumonia.

It is not our intention in this place to discuss the interesting theoretical implications of this penicillin schedule, for they will be alluded to in a separate report dealing with penicillin blood levels in these patients.<sup>11</sup> Suffice it to say here that very high blood levels were found one hour after the initial dose of penicillin and measurable levels for at least six hours afterwards.

## NEW PENICILLIN PRODUCTS FOR SUSTAINED EFFECTS

LEO LOEWE, M.D., ALBERT E. SOBRI, PH.D. AND FRANK ALTMAN-WERBER, PH.D.  
BROOKLYN, N. Y.

THESE studies were intended to devise penicillin preparations which would consistently yield prolonged and enhanced blood serum levels following a single subcutaneous or intramuscular injection. The ultimate objective was to develop a clinically effective slowly and wholly absorbable, nontoxic product which could also be adapted for oral use.

Two major approaches were explored.

One approach was to encase crystalline salts of penicillin in protein, preferably of nonantigenic type such as blood serum of the same species or gelatin. The resulting penicillin protein complex was then insolubilized with formaldehyde or with a heavy metal salt which formed insoluble derivatives with both penicillin and protein. The cations employed were those required by the body, namely ferric and cupric salts.

The other approach was to suspend these penicillin preparations or crystalline Na penicillin "G" in Tween 20 (polyoxyalkylene derivative of sorbitan monolaurate). \* This was predicated on the hypothesis that Tween 20 retards penicillin excretion by attaching itself to lipids and lipoproteins at one end and to penicillin at the other end which results in formation of a larger molecule. The possibility of a Caronamide like effect was also considered.

### METHODS

#### (A) *Technique of Preparation of Formaldehyde Treated Penicillin Protein Mixtures—*

- 1 1 Gm Na (or Cu) penicillin and 0.5 to 2.5 Gm gelatin, in 15 ml  $H_2O$ , are dehydrated while frozen.
- 2 The dried mixture is treated with 5 ml of 40 per cent formaldehyde in 125 ml acetone overnight, at 0 to 5°. Acetone is employed because in it penicillin is stable and both the penicillin and formaldehyde treated gelatin are insoluble.
- 3 The penicillin containing precipitate is filtered, dried in vacuo and finely ground.

#### (B) *Preparation of $Cu^{++}$ or $Fe^{+++}$ Penicillin Protein Mixtures—*

- 1 To 0.6 Gm penicillin dissolved in 15 ml plasma 320 ml of 2.5 per cent  $CuSO_4$ , 7  $H_2O$  or  $FeCl_3$  are added.
- 2 The penicillin containing precipitate is filtered, washed with  $H_2O$ , dried in vacuo, and finely ground.

(C) For orientation purposes all products were first tested in animals. Experiments were carried out as a rule with single dosages equaling 300,000 O.U. penicillin. Potency controls assays were done by both biological and colorimetric methods. The insolubilized penicillin protein complex first had to be trypsin digested in order to release the penicillin for assay.

(D) Blood samples were drawn periodically over a span of twenty-four to forty-eight hours for determination of penicillin levels. In evaluating some preparations the penicillin

content of the urine was also estimated in order to establish the extent and duration of penicillin elimination

It might be stated that our serum penicillin assay method employing *Streptococcus pyogenes* C203 as test organism yields generally and, at times, appreciably lower values than the Food and Drug Association assay method which uses the *Bacillus subtilis* as test organism.<sup>3,4</sup> Therefore, recorded data with the streptococcus C203 system, as a rule, are on the conservative side

Fig. 1—Penicillin blood levels in rabbits following single subcutaneous dose of formaldehyde treated penicillin gels

#### EXPERIMENTAL OBSERVATIONS

At the outset the products were tested in rabbits by direct implantation under the skin in open gelatin capsules to obviate any influence of a vehicle. As may be seen in Fig. 1, the injection of crystalline Na penicillin "g" in saline fails to show measurable blood serum levels after nine hours. By contrast with these controls prolonged effects are noted up to forty-five hours with the penicillin-gel implants and up to twenty-four hours with the same products suspended in saline and injected subcutaneously.

The formaldehyde-treated penicillin gels<sup>a</sup> were mechanically ground to particle sizes permitting injection through an 18 or 20 gauge needle. Because the resultant fine, insoluble, free-flowing powders tended to settle out in saline, they were suspended in ethylene-glycol and in Tween 20. While ethylene-glycol allowed ease of handling as compared with the gels suspended in saline, the measurable penicillin serum values were about the same, enduring for over twenty-four hours. However, the same gels suspended in Tween 20 reflected not only the stabilizing property but also the additive, prolonging, and enhancing effects of Tween 20, the composite result was marked prolongation of

<sup>a</sup>Referred to in illustrations as CH O Gels

Fig. 2.—Comparative penicillin blood level in rabbits following single subcutaneous dose of formaldehyde treated penicillin gel suspended in saline, ethylene glycol and Tween 20

Fig. 3.—Penicillin blood levels in rabbits following single subcutaneous dose of metal penicillin protein mixtures

detectable penicillin levels for a span of forty hours with relatively high values for thirty four hours (Fig. 2)

These singular effects were probably accomplished in a twofold manner, (1) the insolubilized penicillin protein complexes were slowly degraded in the

tissues by enzymatic action harmless to penicillin, and (2) the liberated penicillin combined with the Tween 20 which then exerted its augmenting action

Animal experiments were also conducted with copper- and iron-penicillin-protein mixtures (Fig 3) The penicillin values for these copper and iron complexes were compared with formaldehyde-treated gels suspended in Tween 20 The metal products yielded flatter curves suggesting that they dissociated less readily This is in keeping with published data<sup>5</sup> that metal penicillin products generally do not break down readily in vitro and dissociate but slowly in vivo Prolonging effects are nevertheless apparent, levels being present up to twenty-six hours with the copper and up to thirty hours with the iron products The formaldehyde-treated gels in Tween 20 still evidence the most conspicuous prolonging and enhancing effects

Comparison of graphs showing the average blood levels obtained after subcutaneous injections of 300,000 O U of penicillin in Tween 20 and in saline shows that Tween 20 per se has prolonging and enhancing properties, thirty-four hour detectable levels as against nine-hour control levels

In order to explore further this phenomenon and elucidate its mechanism, animal experiments were done as recorded in Table I Each experiment was carried out with a single dose of 500,000 O U crystalline Na penicillin "g"

TABLE I PENICILLIN SUSTAINING AND/OR ENHANCING EFFECTS OF TWEEN 20 IN RABBITS

EXPERIMENT	BLOOD LEVELS OXFORD UNITS PER ML OF SERUM							
	16 HR	20 HR	24 HR	28 HR	32 HR	40 HR	48 HR	67 HR
Control—5 ml Tween 20 sc	0	0	0					
Repeat in 3 hours sc								
Control—Na Penicillin G 500,000 O U in saline sc	0	0	0					
Na Penicillin G 500,000 O U in 5 ml Tween 20 sc	15		0.5	0.5	0.75		0.15	
5 ml Tween 20 sc r flank, 3 hours later Na Penicillin G 500,000 O U sc l flank	15	15	0.375			0		
5 ml Tween 20 sc, repeat in 3 hours sc, followed in 3 hours by Na Penicillin G 500,000 O U in saline sc	3.75		3.7	0.375		0.75	0.5	0.15

It was evident from these studies in rabbits that

- 1 Tween 20 subcutaneously had of itself no antibiotic effects
- 2 Penicillin in saline subcutaneously gave no detectable levels at and after sixteen hours
- 3 Injection of the penicillin mixed in Tween 20 yielded appreciable levels for forty-eight hours

4 The prolonging property of Tween 20 was observed even though it was injected separately three hours before the penicillin and at a different site. Substantial penicillin levels were obtained for twenty four hours.

5 The combination of Tween 20 and penicillin necessary for prolonging and enhancing effects may occur in the blood as shown in the last of this series of tabulated animal experiments. Here two separate subcutaneous injections of Tween 20 were given three hours apart, six hours after the first and three hours after the second Tween 20 injection, penicillin in saline was given intravenously. Prolongation was striking and persisted for sixty seven hours.

Fig 4—Influence of protein content of formaldehyde treated penicillin gels on sustaining blood levels following single intramuscular dose in human beings

The principles embodied in these various preparations have been applied in human subjects. While our studies in this direction are by no means complete, *similar prolonged effects were noted following a single dose injection of insolubilized penicillin gel suspended in saline or Tween 20 and a similar dose injection of Na penicillin "G" in Tween 20.*

In the case of the formaldehyde treated penicillin gel it was not possible to translate the results of animal experimentation into clinical use without revision of the preparation. For instance, in the matter of the protein content it was found that when the proportion of protein to penicillin was maintained at 2 1/2 to 1, penicillin could be detected in body fluids, because of retarded degradation of the protein penicillin complex for as long as ninety six hours after the injection which was as far as the tests were pursued. Under these circumstances detectable blood levels were maintained for only twelve hours. However, when the proportion of protein to penicillin was reduced to 1/2 to 1, detectable blood levels of a relatively high order were maintained for twenty four hours (Fig 4). Apparently the reduction in protein content resulted in release of the penicillin at a more rapid and even tempo.

The penicillin sustaining and/or enhancing properties of Tween 20 were also manifested in human subjects during the following series of experiments (Table II)

1 Crystalline Na penicillin "g," 500,000 O U in saline injected intra muscularly gave no detectable blood levels at eight hours or thereafter

2 Crystalline Na penicillin "g," 500,000 O U dispersed in 5 ml of Tween 20 and injected intramuscularly yielded sustained and enhanced effects for twenty hours

3 In this experiment the patient was given 5 000 000 O U of Na penicillin daily by continuous venoclisis. Control blood assays on this dosage schedule were 5 O U per milliliter of serum. Tween 20 was given orally, 10

TABLE II PENICILLIN SUSTAINING AND/OR ENHANCING EFFECTS OF TWEEN 20 IN HUMAN BEINGS

EXPERIMENT	BLOOD LEVELS OXFORD UNITS PER ML OF SERUM						
	2 HR	4 HR	6 HR	8 HR	12 HR	16 HR	20 HR
Control--Na Penicillin G 500,000 O U in saline i m		10		0.012	0	0

ml every four hours for five doses. An enhancing effect was observed beginning four hours after and persisting for twenty hours after the last dose of Tween 20 when it reached a peak level of 35 O U per milliliter of serum which was seven times the control value.

4 In the final experiment of this series, 500 000 O U of a protein penicillin complex were given orally in the morning on a fasting stomach. Ten milliliters of Tween 20 were given orally every two hours for the duration of the experiment. Therapeutic penicillin blood values were obtained throughout the entire sixteen hours of this test.

Further studies were carried out with oral administration of formaldehyde treated penicillin products. Data thus far indicate that detectable levels up to twenty-four hours have been obtained following oral administration of 300,000 O U of the protein-penicillin complex with and without the conjoint use of Tween 20. As indicated by *in vitro* tests, the insolubilized protein-penicillin complex is gradually digested by trypsin which has no destructive influence on the slowly liberated penicillin\*. These investigations are still being pursued in

\*The oral use of Tween yielded additional prolongation effects. This was probably achieved by retarding the excretion of penicillin in the manner previously suggested.

an effort to develop a consistently effective predictable long acting medium for the oral administration of penicillin.

The factors responsible for this prolonging and enhancing action of Tween 20 in both rabbits and human subjects are still being investigated as are other facets of this problem. It is of interest to note that comparable studies with heparin show similar results these will be presented later in detail. Studies thus far indicate that the Tween effect is not due to impairment of renal function in the usual sense. Tween 20 and a kindred compound (polyoxyalkylene derivative of mannitan monolaurate) were found to be innocuous in long term feeding experiments in animals and no toxic manifestations were reported following its parenteral and oral use in human beings. No side effects were observed in human subjects after ingestion of capsules containing the protein penicillin products or following Tween taken orally in divided doses totaling 100 milliliters.

#### SUMMARY

Prolongation of serum penicillin levels were observed in rabbits and human beings following single subcutaneous or intramuscular injections of formaldehyde treated protein penicillin preparations. Significant sustaining and enhancing effects were noted following the administration of the insolubilized protein penicillin complexes or crystalline Na penicillin G<sup>1</sup> suspended in Tween 20. The mechanism of this property of Tween 20 was investigated. Measurable penicillin levels were obtained in human subjects up to twenty four hours following ingestion of a single dose of penicillin gel, alone or in combination with Tween. Further studies are in progress with the ultimate objective of developing practical penicillin sustaining and enhancing products for subcutaneous intramuscular and oral use in human beings.

The authors are indebted to Mr. Sidney Noble for technical assistance.

## THE TURBIDIMETRIC ASSAY OF HYALURONIDASE

SIBYLLE TOLKSDORF, PH D, MARIAN H MCCREADY, B A, D ROY MCCULLAGH,  
PH D, AND ERWIN SCHWENK, D Sc  
BLOOMFIELD, N J

THE various methods suggested for the quantitative determination in vitro of the enzyme hyaluronidase are dependent on its property of hydrolyzing hyaluronic acid. During hydrolysis, the reducing properties of a solution of hyaluronic acid are increased, the viscosity is decreased, and as observed by Meyer and Palmer,<sup>1</sup> the ability of hyaluronic acid to precipitate with acidified protein is decreased. These observations served as the basis of the viscosity test, the mucin clot test, and the turbidimetric assay method for hyaluronidase activity. A comprehensive review of the entire problem of hyaluronidase and hyaluronic acid, including a discussion of the assay techniques, has been prepared recently by Meyer.<sup>2</sup>

The present investigation deals with the turbidimetric method of assay which has been developed by Seastone,<sup>3</sup> Kass and Seastone,<sup>4</sup> Leonard, Perlman, and Kurzrok,<sup>5</sup> and Dorfman and Ott.<sup>6</sup> We have studied various factors which might influence the sensitivity and accuracy of the assay in order to obtain optimal conditions for hydrolysis and development of turbidity. On the basis of these studies it has been possible to devise a more satisfactory technique for the turbidimetric assay of hyaluronidase and to define a unit for the enzyme.

### A. METHOD AND MATERIALS

The principles of the assay technique used in the first part of this study were essentially those described by Meyer.<sup>2</sup> Enzyme and substrate were incubated for thirty minutes at 37.5° C in an acetate sodium chloride buffer at pH 6. Turbidities were then developed by diluting the system with pH 4.2 acetate buffer and adding acidified protein solution. The turbidities were read in a Summerson Klett photoelectric colorimeter which had been standardized in terms of light transmission against a Beckman spectrophotometer. The Klett readings, obtained with a blue filter, can be expressed as percentage transmission for wave length 680 mμ by using the following formula: % transmission = 94.53 - (0.197 × Klett reading). The results of the assays were expressed in Turbidity Reducing Units (TRU) tentatively defined as the amount of enzyme which will reduce the turbidity produced by 0.2 mg of hyaluronic acid to that produced by 0.1 mg of hyaluronic acid in accordance with previous authors.<sup>2, 4</sup> This definition was used during the experimental part of this paper which led to the establishment of a new unit.

Hyaluronic acid was prepared from human umbilical cords by a modification of the method of Rogers.<sup>7</sup> Both sodium and potassium salts were used in these studies. Hyaluronidase was prepared from bovine testes by ammonium sulfate fractionation. Acidified proteins were prepared from various sources. Serum or plasma was diluted with 9 parts of 0.5M acetate buffer at pH 4.2 and adjusted to pH 3.1 with 4N HCl.

From the Biochemistry Department, Schering Corporation.  
Received for publication July 29, 1948.

## B ENZYME SUBSTRATE REACTION

1 *Influence of Sodium Chloride*—It has been noted that the apparent enzymatic activity of testicular hyaluronidase depends greatly on the nature and concentration of the electrolytes present. In a given buffer system sodium chloride of certain concentrations seems to have a specific accelerating influence on the velocity of this enzymatic reaction.<sup>8,9,10</sup> We therefore studied the influence of sodium chloride on the activity of hyaluronidase. A preparation of enzyme was used which gives an assay of 27 TRU per milligram when incubated with substrate in 0.1M acetate buffer pH 6 containing physiologic saline (0.15M). Using pH 6 acetate buffer with varying amounts of sodium chloride, we found that the apparent units per milligram of hyaluronidase ranged from 5 in the absence of sodium chloride to 13 in the presence of 0.07M sodium chloride. At higher concentrations of sodium chloride the apparent enzymatic activity decreased. It is desirable that the assay values of the enzyme should reflect the activity of the enzyme under physiologic conditions. Since physiologic salt solution (0.15M) gives very satisfactory assay values this concentration of sodium chloride has been employed.

2 *Heat Inactivation*—In order to avoid further hydrolysis of hyaluronic acid after the thirty minute period of incubation with hyaluronidase the reaction was stopped by immersing the tubes in a 60° C. water bath for ten minutes. It was found that this temperature was sufficient to inactivate hyaluronidase solutions.

## C DEVELOPMENT OF TURBIDITY

1 *Stabilization of Proteins by Aging*—The assay method as originally published called for the use of horse serum as the protein indicator to measure the quantity of hyaluronic acid remaining after enzymatic hydrolysis. Our observations indicated that the age of the protein solution was much more important than had been recognized by earlier workers.<sup>2</sup> We found that immediately after diluting fresh serum there was no consequential difference between the turbidity caused by a given amount of this serum with 0.1 mg. and 0.2 mg. of hyaluronic acid. Therefore assays performed with freshly diluted serum will not have the desired degree of accuracy. It was noted however, that after standing in the cold for some time, the same acidified serum would give greater turbidities with hyaluronic acid, and that the spread between the blanks also increased with time. The effect of aging over a period of three weeks was therefore investigated.

In this study we used, as the source of protein, freshly collected as well as commercially available horse serum, human serum obtained from healthy volunteers and human plasma purchased from Cutter Laboratories. In a search for a more stable protein, we included in this investigation such purified protein fractions as crystalline horse serum albumin prepared by the method of Svedberg and Sjogren,<sup>11</sup> crystalline egg albumin prepared by the methods of Cole<sup>1</sup> and Longworth and co workers<sup>12</sup> and Fraction V of bovine plasma albumin, prepared by Armour Laboratories according to the method of Cohn.<sup>14</sup> The

After bleeding

† Age since bled

‡ Crystalline horse serum albumin.

§ Bovine plasma albumin fraction V

sera and plasma were diluted and acidified to pH 3.1 as mentioned. Crystalline horse serum albumin and egg albumin were dissolved in buffer containing 0.5M acetate, pH 4.2 and 0.1M mandelic acid as stabilizer<sup>15</sup> at a concentration of 10 mg per milliliter and then adjusted to pH 3.1. With Fraction V of bovine plasma albumin, it was necessary to use a concentration of 20 mg per milliliter in order to get satisfactory turbidities. The solutions were kept at 5° C during the period of study.

Numerous assays of hyaluronidase were performed, using as indicators the acidified protein solutions (a) made up freshly, (b) after standing in the cold for one week, (c) after standing in the cold for three weeks. These experiments are recorded in the left columns of Table I which includes the turbidities obtained with hyaluronic acid (0.2 mg and 0.1 mg blanks) incubated in the absence of enzyme, the difference  $\Delta$  between the blanks, and the assay results in TRU per milligram. With locally collected horse serum, human serum, and Lederle horse serum, none of which contained a preservative, the spread between the turbidities of the blanks increased progressively with age. At the same time, the apparent units per milligram decreased. Similar changes were observed to a lesser degree with Parke, Davis horse serum, pooled human plasma and crystalline horse serum albumin. It therefore appeared that these proteins were already partially stabilized\*. On the other hand, the changes in the turbidities of the blanks obtained with bovine plasma solution aged in the cold for seven and twenty-one days were most striking. Aging by this procedure failed to give sufficient stabilization of the protein reagent to assure uniform assay results.

Crystalline egg albumin proved to be so unstable under the conditions of our experiments that its use had to be discontinued.

*2 Stabilization of Proteins by Heating*—Since aging in the cold did not fully stabilize the acidified proteins within a period of three weeks, an effort was made to accelerate the aging process by heating. The results are included in the right columns of Table I. Aliquots of the solutions used in the study on aging were heated to 100° C on the days indicated in the table and used for assays. In several instances, the heated solutions were kept at 5° C for seven and twenty-one days respectively and then used for assays.

The results indicate that the heated proteins gave considerably higher turbidity readings with hyaluronic acid (0.2 mg and 0.1 mg blanks) than observed with the unheated proteins. The differences between the turbidities of the blanks were much greater and showed less variation. The units per milligram calculated from these blanks were lower but much more constant (see Table I). Protein solutions, once heated, gave the same turbidities and assay results with hyaluronic acid after standing in the cold for seven and twenty-one days respectively. It should be mentioned that the bovine plasma albumin solutions had been stabilized by the improved heating technique described below which results in a lowering of the assay values.

\*Parke Davis horse serum contained 0.4 per cent purified cresol and the human plasma contained 5 per cent dextrose and 1:15,000 phenylmercuric benzoate.

Fig 2—Influence of heat-stabilization of acidified plasma on apparent enzymatic activity of hyaluronidase

Because it is readily available to most investigators, all subsequent experiments have been carried out with human plasma

*3 Time Factor in Heat Stabilization*—From the results obtained it appeared that heated proteins were quite suitable for developing turbidities with hyaluronic acid. In order to further reduce the variations in the results the heat stabilization of protein solutions was studied in greater detail. Human plasma diluted and acidified to pH 3.1 as described was chosen for this investigation. In the previous experiments the plasma had been brought to a boil directly on an electric hot plate. Since this technique may not be entirely reproducible samples of plasma were heated under various controlled conditions and for different lengths of time. In all experiments 50 ml of diluted acidified plasma were placed in each of six test tubes measuring 25 by 200 mm. In each instance one sample of plasma was used without heating and the other samples were heated for various lengths of time. In the first five tests (Table II) the tubes with the plasma were heated in a 2 liter beaker containing 1 liter of boiling water. The other tests were performed by immersing the tubes containing plasma in a large steam heated water bath. The second procedure appeared in general to cause more rapid heating. At the completion of various periods of heating the tubes were removed from the bath and chilled. The protein solutions were then used as indicators in the determination of hyaluronic acid. The data obtained from eight heating experiments are summarized in Table II and the averaged results are illustrated in Figs. 1 and 2.

It can be seen from Fig. 1 that the unheated plasma proteins gave very low turbidities with hyaluronic acid. After heating however the proteins precipitated more readily with the substrate and the difference in the turbidities of the two blanks increased with the length of time of heating. Fig. 2 represents graphically the progressive decrease in the units per milligram under these conditions. The apparent enzymatic activity dropped sharply when plasma heated to 80 and 90° C was used as a protein indicator. With prolonged heating however, the curve leveled off. It may be concluded that plasma heated at 99° C for thirty minutes gives the most desirable results both in regard to the spread of the turbidities of the blanks and the accuracy of the assays.

*1 Influence of Hydrogen Ion Concentration on Heat Stabilization of Acidified Proteins*—Human plasma was diluted 1:10 with pH 4.2 acetate buffer, adjusted to hydrogen ion concentrations varying from 2.5 to 4.2 and heated as described. Assays were performed using these protein solutions as indicators. The final pH of the solutions in which turbidities were developed was found to vary only from 4.12 to 4.18.

Human plasma adjusted to pH 4.2 proved completely unsatisfactory in our hands because it coagulated upon heating. In this connection it is interesting to note that diluted horse serum could be heated at pH 4.2 without coagulating. However the blanks obtained with horse serum adjusted to pH 4.2 were too low and too close together to give the greatest possible accuracy.

The experiments carried out with human plasma at pH 2.5, 3.1, and 3.7 are shown in Fig. 3. Using plasma heated at these hydrogen ion concentrations

Fig 3.—Turbidities obtained with hyaluronic acid and human plasma heat-stabilized at different hydrogen-ion concentrations

Fig 4.—Influence of plasma concentration on turbidities obtained with hyaluronic acid

the blank values for both concentrations of hyaluronic acid showed a maximum turbidity with plasma heated at pH 3.1. Also, the spread between the blanks was at a maximum at this pH. This hydrogen ion concentration may, therefore be considered most suitable for stabilizing plasma proteins. The assay results for the hyaluronidase fraction used gave 33, 34, and 20 TRU per milligram with plasma heated at pH 2.5, 3.1, and 3.7 respectively.

*5 The Influence of Protein Concentration on the Turbidity produced by Hyaluronic Acid*—The turbidity produced in the assay procedure depends not only on the amount of hyaluronic acid but also on the amount of protein in the system. With this in view, we have added various concentrations of heat stabilized plasma to hyaluronate in a buffer system identical to that used in the assay. The results are presented graphically in Fig. 4. Plasma was used at dilutions varying from 1:25 to 1:160 or 40 per cent to 0.625 per cent concentrations. Curves are plotted of the turbidities obtained with these protein solutions and 0.1 mg and 0.2 mg of hyaluronic acid. In both instances, it was found that the turbidity reached a maximum and then decreased upon the addition of more plasma. Whether the decrease in turbidity in the presence of excess plasma is the result of alteration in particle dispersion or increased solubility of the precipitate is not known. The maximum turbidity using 0.2 mg of hyaluronic acid is produced with plasma diluted 1:5, the maximum turbidity using 0.1 mg of hyaluronic acid is produced with plasma diluted 1:10.

#### D. SUBSTRATE

*1 Preparation of Hyaluronate From Umbilical Cords*—Human cords were washed free of blood and collected under 2 per cent aqueous phenol. They were removed from the phenol solution, passed once through a meat grinder and twice through an Eppenbrech colloid mill and weighed. Two and one half kilograms of ground material were extracted three times for twenty-four hours with 9, 6, and 6 liters of 1 per cent aqueous phenol respectively. The crude hyaluronate was precipitated from the extracts in the form of a mucin clot by adding acetic acid to a concentration of 0.2 per cent. The precipitate was dried with alcohol and acetone and extracted with alkaline water at pH 8 (KOH or NaOH) at a concentration of 0.5 per cent. The extract was precipitated with  $1\frac{1}{2}$  volumes of denatured alcohol saturated with acetate, and dried. The alkaline extraction and alcohol precipitation were repeated once more.

In order to remove the proteins still present, the second alcohol precipitate was dissolved in water at pH 8 to a concentration of 0.5 per cent and shaken with 5 per cent by volume of a 1:1 mixture of chloroform butanol and centrifuged. This procedure was repeated with fresh chloroform butanol until no more protein was precipitated upon centrifugation. For further clarification, the solution was shaken with bentonite, centrifuged and precipitated with 2 volumes of denatured alcohol to which sodium or potassium acetate was added in amounts sufficient to induce flocculation. The yield was approximately one half gram per kilogram of ground cords.

2 *Properties of the Substrate*—Analytic data for various substrate batches prepared from umbilical cords are given in Table III. The preparations were chemically similar, the average nitrogen was 3.13 per cent, the average potassium calculated as potassium sulfate was 10.1 per cent. The viscosities varied from 5.4 to 11. The turbidities produced with stabilized plasma were all of the same

Fig. 5—Standard curve of four substrate preparations

magnitude but it has been our experience that the variations from batch to batch of hyaluronate are such that standard curves must be prepared for each batch. A standard curve obtained with 0.04 to 0.8 mg of hyaluronate and a constant amount of human plasma stabilized at 99° C for thirty minutes is demonstrated in Fig. 5. When plotted on semilogarithmic paper, the standard curve is S shaped as observed before by Meyer.<sup>2</sup> It gave a straight line for the turbidity readings between 250 and 125 which, in terms of light transmission, corresponds to a range of 45 to 70 per cent. The standard curves for all preparations were essentially parallel over the entire range.

## 1 THE UNIT OF HYALURONIDASE

Different batches of hyaluronate vary in purity and degree of polymerization and therefore may produce different turbidities at a given concentration. For assay purposes, these variations can be eliminated by using all substrate preparations at a standard turbidity rather than on a constant weight basis as originally suggested by Kass and Seistone.<sup>4</sup>

The hydrolysis of hyaluronate proceeds as a monomolecular type reaction expressed by the formula  $k = \frac{1}{t} \log \frac{a}{(a-x)}$ .<sup>5</sup> This relationship is true within those limits of substrate concentration which give a straight line standard curve. The assay of hyaluronidase can be carried out on this portion of the curve by choosing an initial turbidity of  $50 \pm 5$  per cent light transmission or 200 to 250 turbidity readings on the Klett instrument. Under the conditions of our assay method as described below it is therefore possible to establish a unit for measuring activity of the enzyme. One unit of hyaluronidase is defined as the amount which will hydrolyze one half of a quantity of substrate sufficient to cause a turbidity corresponding to  $50 \pm 5$  per cent light transmission.

## 2 ASSAY METHOD FOR HYALURONIDASE

1 *Preparation of Stock Solutions*—(a) Two buffers are used both made from stock solutions of 0.5M sodium acetate and 0.5M acetic acid. One tenth N acetate buffer pH 6.0 is made by combining 3 ml of 0.5M acetic acid, 97 ml of 0.5M sodium acetate and 4.384 Gm of sodium chloride and diluting to 500 ml with water. This gives a concentration of 0.15M sodium chloride. Half N acetate buffer pH 4.2 is made by combining 130 ml of sodium acetate with 370 ml of 0.5M acetic acid. The pH of the buffers should frequently be checked and adjusted if necessary.

(b) Potassium hyaluronite is dissolved in the 0.1M acetate sodium chloride buffer, pH 6.0. On the basis of the standard curve a concentration is chosen which in the assay will give a transmission of  $50 \pm 5$  per cent at a wave length of 600  $m\mu$  which corresponds to a turbidity reading of 200 to 250 in the Summer son Klett photoelectric colorimeter using a blue filter. For many preparations of hyaluronate, this turbidity will be reached by using a concentration of 0.4 mg per 1.0 ml buffer. Otherwise, the concentration of hyaluronate should be adjusted to give a turbidity reading of about 225. The solution is stored at 5° C and is warmed to room temperature before use. It can remain at 5° C without changing, over a period of at least two weeks.

(c) Hyaluronidase is dissolved at room temperature, in the pH 6.0 acetate sodium chloride buffer. The concentration is chosen so that 1 ml contains approximately 3 units. The enzyme solution is used immediately after being made.

<sup>5</sup> In this formula  $k$  = velocity constant  $t$  = time  $a$  = initial concentration of substrate  $x$  = quantity of substrate hydrolyzed during time  $t$ .

(d) Acidified protein solution is prepared by diluting human plasma 1 to 10 with 0.5M acetate buffer, pH 4.2 and adjusting to pH 3.10 with 4N hydrochloric acid. This solution is distributed in 50 cc portions in test tubes measuring 25 by 200 milliliters. These tubes are placed in a boiling water bath. After the plasma reaches temperature equilibrium (99° C), it is kept in the bath for thirty minutes, when it is immediately cooled to room temperature by immersion in ice water. The plasma can be kept in the cold for at least two weeks.

2 *Incubation of Enzyme and Substrate*—Seven Klett tubes are set up for each assay as shown in Table IV. The solutions are mixed and the tubes are

TABLE IV SETUP OF TUBES FOR HYALURONIDASE ASSAY

KLETT TUBE	SUBSTRATE SOL	pH 6 BUFFER	ENZYME SOL
#1	5 ml	5 ml	—
2	25	75	—
3	5	—	5 ml
4	5	1	4
5	5	2	3
6	5	3	2
7	5	4	1

immersed in a constant temperature water bath kept at 37.5° C for thirty minutes. In order to inactivate the enzyme, the tubes are immersed in a 60° C water bath for ten minutes. They are cooled to room temperature under running water. As a rule, not more than three enzyme fractions and the blanks are assayed simultaneously (seventeen tubes). If more tests have to be performed, they are staggered in order to keep the time relations constant.

3 *Development of Turbidities*—To each Klett tube are added 3 ml of 0.5M acetate buffer, pH 4.2, followed by 1 ml of acidified human plasma treated as described. The contents of each tube are mixed and then allowed to stand at room temperature for thirty minutes. The turbidities are read in the Summerson-Klett photoelectric colorimeter with a blue filter or any other suitable instrument. The zero reading of the instrument is set with a tube containing 1 ml of pH 6 acetate sodium chloride buffer, 3 ml of pH 4.2 acetate buffer and 1 ml of acidified, stabilized human plasma solution.

All Klett tubes are numbered permanently and their absorption which is variable is determined with the same mixture which is used to set the zero of the instrument. For the zero reading, only tubes with zero absorption are used. The readings of the seventeen tubes in the assay are corrected to zero absorption.

4 *Method of Calculation*—The corrected turbidity readings are plotted against concentration of enzyme. This gives a straight-line curve since the Klett instrument has a logarithmic calibration. The enzyme concentration corresponding to the turbidity of the lower blank is read from the graph. This indicates the amount of enzyme containing 1 turbidity reducing unit.

#### G THE ACCURACY OF THE ASSAY

In order to determine the error in this procedure, seventy-one assays were made on thirty-two different days by two different technicians, using the same

sample of enzyme. The mean value of all determinations was 27 TRU per milligram. The results were treated statistically and the standard deviation of a single observation is 10. The distribution of the assay results is shown in Fig. 6.

Fig. 6—Distribution of seventy one assay results

#### CONCLUSIONS

The assay method of Kass and Seastone<sup>4</sup> has been used with modifications by Leonard and associates and Meyer. Recently Dorfman and Ott<sup>5</sup> have published a critical investigation of various phases of the turbidimetric technique. Having used the turbidimetric method for several years in this laboratory, we find it important to emphasize the following points in order to clarify some of the discrepancies in the results obtained by different laboratories.

The enzymatic hydrolysis of hyaluronic acid is greatly influenced by the nature and concentration of the buffers employed. We find that a suitable buffer is 0.1M sodium acetate pH 6.0, containing 0.15M sodium chloride. This is close enough to the optimum salt concentration for hyaluronidase activity and measures the enzymatic activity under physiologic conditions.

Since the accuracy of the method is dependent upon the length of time of hydrolysis, it is expedient, in performing large numbers of routine assays to inactivate the enzyme after the thirty minute incubation period. This can readily be achieved by immersing the reaction tubes in a water bath of 60° C for ten minutes.

The turbidimetric method of measuring the amount of hyaluronic acid remaining after enzymatic hydrolysis is based on the interaction between hyaluronic acid and acidified protein. It has been mentioned by Seastone<sup>4</sup> and by

Leonard and co-workers<sup>5</sup> that the age of the protein solution influences the development of turbidities. As we have shown, aging by rigidly standardized heating will insure reproducible and accurate results. The protein is denatured during the stabilizing process and as a result becomes more precipitable. This results in a greater turbidity when the protein reacts with hyaluronic acid. The slopes of the standard curves obtained with increasing amounts of hyaluronic acid and stabilized protein are much steeper than those obtained with unheated protein. This increases the difference in the turbidity of the two blanks and the accuracy of the assay. It is also important to age the proteins at the proper pH in order to obtain maximum turbidities. Under the conditions of our experiments, aging should be done at pH 3.1.

In the present study, all assays have been carried out with hyaluronate prepared from umbilical cords. Different batches of substrate vary somewhat in their chemical and physicochemical properties and give different turbidities with acidified protein. For assay purposes, these variations can be eliminated by adjusting all substrate solutions to a standard turbidity.

By utilizing the information collected during this study it has been possible to arrive at a method for the assay of hyaluronidase which is accurate, reproducible, and permits the definition of a unit without reference to a standard.

#### SUMMARY

1. Irregularities in the turbidimetric assay of hyaluronidase have been demonstrated and traced to the protein employed in forming the turbidity with the substrate hyaluronic acid.

2. Various proteins have been investigated and methods devised for their stabilization by heating under specified conditions.

3. Other factors influencing the accuracy of the method have been studied.

4. A study of the substrate has been made and methods of preparation and use have been described which give constant assay results from batch to batch.

5. An assay method for hyaluronidase using heat-stabilized human plasma is described.

6. A unit for hyaluronidase activity has been defined and discussed.

The authors wish to thank Anne H. Kennison and James W. Cassidy for their assistance in this investigation.

# SICKLE CELL DISEASE STUDIED BY MEASURING THE SURVIVAL OF TRANSFUSED RED BLOOD CELLS

SHEILA T E CALLENDER, M D,\* JAMES F NICKEL, M D, AND  
CARL V MOORE, M D, DEPARTMENT OF INTERNAL MEDICINE,  
WASHINGTON UNIVERSITY AND BARNES HOSPITAL, ST LOUIS, MO.,  
AND E O POWELL, OXFORD, ENGLAND

THE investigations to be described in this report were designed (1) to study the pathogenesis of the increased hemolysis in patients with sickle cell anemia, (2) to determine how sickle cell anemia and sickle cell trait erythrocytes differ in terms of survival time following transfusion, and (3) to search for evidence that forms of sickle cell disease intermediate between the anemia and the trait might exist. Survival of transfused red blood cells was measured with the Ashby technique of differential agglutination<sup>1</sup>. Observations were made (1) on the survival of normal cells transfused into patients with sickle cell anemia, (2) on the survival of cells transfused from donors with the sickle cell trait and from donors with sickle cell anemia, (3) on the effect of high tensions of inspired oxygen on the survival of cells transfused from patients with sickle cell anemia, and (4) on the survival of sickle cell trait cells transfused into a subject with chronic cyanosis. The results clearly indicate that the abnormal hemolysis of sickle cell anemia is caused by an intraerythrocytic defect which makes the cells less able to stand the trauma of circulation. Trait erythrocytes, on the other hand, survive normally.

## METHODS AND EXPERIMENTAL CONDITIONS

The modified Ashby technique of Dacie and Mollison<sup>2</sup> was used for determining the nonagglutinable counts. Differentiation of transfused cells was made by either the ABO groups or the MN groups†. Counts were made from venous blood at frequent intervals following transfusion, usually by two independent observers. Each observer took the average of at least four counts. In earlier experiments a crude measure of survival of transfused sickled cells in normal subjects was made by counting the percentage of sickle cells in sealed wet preparations of finger blood after forty eight hours. Later, to insure full sickling, CO was bubbled for twenty minutes through samples of venous blood kept under paraffin oil, the cells were then fixed with 10 per cent formalin in 0.85 per cent sodium chloride. Moist preparations were made from this blood and the number of abnormal forms found in 100 cells was counted. The absolute number of sickle cells was calculated from this figure and the total red cell count. Red blood cell pipettes and hemocytometer chambers were standardized by the United States Bureau of Standards. Wet preparations were used in Sherman's test<sup>3</sup> for the percentage of sickled cells in venous blood.

Supported in part by the Philipp Hunkel Memorial Research Fund

Presented in part before the Twentieth Annual Meeting of the Central Society for Clinical Research Oct 31 and Nov 1 1947 abstracted in J LAB & CLIN MED 32 1397 1947

†Counts erratic. Curvature appreciable but not significant.

r (the average time of survival of transfused cells) and T (the end point of the curve) are in days from transfusion.

Other symbols see text.

Normal cells for transfusion were obtained from the Blood Bank of the Barnes Hospital. White donors were selected to insure absence of sickling. The blood was less than five days' old when used. Donors with sickle cell anemia or the sickle cell trait were bled by one of us as needed for the experiments, and the cells were transfused within twenty-four hours. Acid citrate dextrose (A.C.D.) solution was used as the preservative and anticoagulant, supernatant plasma was removed immediately before transfusion.

All of the patients with sickle cell anemia showed the characteristic clinical manifestations of the disease, an anemia, reticulocytosis, elevated icteric index, more than 30 per cent abnormal or sickled cells with Shermin's test, and all have required repeated transfusions for support.

Fig 1

"Normal" recipient subjects were patients in the hospital who were either hematologically normal, in which case an equivalent amount of blood was removed immediately prior to the transfusion, or they were women with a moderate hypochromic or normocytic anemia who had recently had a hysterectomy for menorrhagia. They were all negative for the sickling trait.

In the experiments involving continuous inhalation of oxygen, 70 to 80 per cent oxygen was given by an O.E.M. mask. An oronasal mask was used except at mealtimes when a nasal mask was substituted. The flow was kept at 7 to 8 liters per minute and a humidifier was used. A nurse was in constant attendance at the bedside to keep the mask properly adjusted.

### RESULTS

I *The Survival of Normal Cells Transfused Into Patients With Sickle Cell Anemia*—Normal red blood cells were transfused into three different patients with sickle cell anemia. The results (Fig 1, Table I) are in agreement with those of Altmann<sup>4</sup> in that the survival times of the transfused cells were normal.

II *The Survival of Red Cells Transfused From Patients With Sickle Cell Anemia*—Very different results were obtained when the positions of donor and recipient were reversed (Figs 2 and 3). Four normal subjects received blood from patients with sickle cell anemia. In each instance there was a rapid destruction of the majority of the transfused cells. The graphs of survival, however, differed from those found in conditions where there is indiscriminate

destruction of red cells, e g in patients with acquired hemolytic anemia transfused with normal cells<sup>7</sup> There was a rapid initial fall but the speed of hemolysis was not maintained and a small proportion of the sickle cells, varying from case to case, tended to survive for a longer period

Fig 4—Unstained wet preparation of blood of normal recipient (A Tu) showing sickle cells transfused from a patient with sickle cell anemia (B W) about two weeks previously

Survival of the sickle cells was also studied by counts made on sealed moist preparations of finger blood This method did not insure sickling of all potential sickle cells and, therefore, did not give a true measure of survival of the transfused cells Sickling could, however, be demonstrated for about three weeks from transfusion (Fig 4)

One patient (G P), with sickle cell anemia, received blood from another girl (L B) with sickle cell anemia The disappearance of the transfused sickle cells was comparable to that found in the normal recipient subjects, again there was a suggestion of some selective destruction (Fig 5)

III *The Survival of Red Cells Transfused From Donors With the Sickle Cell Trait*—When five healthy, Negro subjects having the sickle cell trait were used as donors, the results were in striking contrast to those obtained with blood

## SURVIVAL OF SICKLE CELLS TRANSFUSED TO A PATIENT WITH SICKLE CELL ANEMIA

Fig 5

## SURVIVAL OF CELLS TRANSFUSED FROM A DONOR WITH SICKLE CELL TRAIT

Fig 6

transfused from patients with sickle cell anemia (Table I) Four of five normal recipients showed normal survival of the transfused trait cells Fig 6 illustrates this result and shows also the close correlation between the nonagglutinable counts obtained by the Ashby technique and the number of surviving cells calculated from sickle cell counts made on venous blood samples treated with  $\text{CO}_2$  The cells from the fifth donor (A H) showed a slightly shorter survival time The recipient in this instance did not report regularly for observations and the data are not entirely satisfactory

One of the donors (F O) with sickle cell trait gave blood on a second occasion for transfusion to the girl (H S<sub>1</sub>) with sickle cell anemia, previously transfused with normal cells The two graphs of survival in this girl were strikingly similar

IV *The Effect of High Tensions of Inspired Oxygen on the Survival of Cells Transfused From Subjects With Sickle Cell Anemia*—The patient G P (vide supra) with sickle cell anemia was given a second transfusion with cells from another donor with sickle cell anemia (B W) This time inhalation of oxygen was started about two hours before transfusion and continued for ten days Eighty per cent oxygen was used initially but this was reduced to 70 per cent on the second day The results are shown in Fig 7 Although destruction of transfused cells was abnormally rapid during the first ten days, it was slower than on the occasion of the previous transfusion When oxygen was discontinued an acceleration in the cell destruction was indicated by an increase in the slope of the graph The initial slope was about  $0.029 \text{ day}^{-1}$ , after withdrawal of oxygen,  $0.112$  The difference is considerable, and the second figure compares well with the initial slope in another recipient (A Tu) receiving blood from the same donor ( $0.116$ )\* Sickle counts made on venous blood samples at intervals by Sherman's technique<sup>3</sup> showed a reduction in percentage of total abnormal plus sickle cells from 36.8 to 10.8 during oxygen inhalation and a corresponding reduction of true sickle cells from 22 to 0.8 per cent As observed previously by Reinhard and co-workers,<sup>8</sup> the percentage of abnormal and sickle cells showed a rise after oxygen inhalation was stopped, in this instance, the abnormal cells increased to 50.8 per cent and completely sickled cells to 39.0 per cent before returning to base line figures

Two similar experiments were planned using normal recipient subjects The first of these (M L) tolerated oxygen somewhat irregularly for only two days During this time the nonagglutinable count had shown little change, whereas subsequently there was a rapid disappearance of transfused cells This cannot, however, be taken as a reliable experiment The second normal recipient subject in this group (Z R) cooperated well She inhaled 80 per cent oxygen for twenty-four hours after transfusion and then 70 per cent for an additional

\*Sometimes the inagglutinable counts are much more erratic than they are here the configuration of the data might possibly have arisen from an unfortunate conjunction of random error The following argument may therefore be made If to the data are fitted any of the survival functions that have been proposed under the hypothesis that the oxygen has had no effect it is found on applying Jeffreys' K test<sup>9</sup> that even for the 4-parameter equations K is less than 0.1 Thus it is highly improbable that the divergence of the data in question from the fitted curves is due to random and not systematic error Further it may be noted that the chance of the observed change in slope occurring just where it does between say ten and thirteen days and not elsewhere is of the order of 0.1 if it is merely accidental

## EFFECT OF INHALATION OF 70% OXYGEN ON THE SURVIVAL OF TRANSFUSED SICKLE CELLS

eight days. There was no significant change in slope of the decay curve on withdrawing oxygen. But this does not necessarily mean that the oxygen had no effect. The slope of the first section was considerably less than might have been expected from a previous experiment with the same donor (0.043 day<sup>-1</sup> as against 0.058).

V *The Survival of Sickle Trait Cells in a Subject With Chronic Cyanosis*—An attempt to accelerate the disappearance of cells transfused from a donor with the sickle cell trait was made by giving a replacement transfusion to a boy with congenital heart disease (Eisenmenger's complex) and extreme cyanosis (Table I). The arterial oxygen saturation was 80.5 per cent as compared with a normal control of 95.5 per cent\*. The survival time of the transfused cells did not differ from that found in normal recipient subjects.

VI *Mathematical Analysis of Results*—Transfusions of normal and sickle trait blood into subjects with sickle cell anemia and of sickle trait blood into normal subjects have in each case led to a decay curve of a linear or gently and uniformly curved character having, with one doubtful exception, a rather well defined end point near 120 days. Curves of this type are such as have been associated with transfusions of normal blood into normal subjects, and to make comparison quantitative, an equation of one of two forms has been fitted to

\*The authors are indebted to Dr John C. Tinsley, Jr. for these determinations.

each set of data. For sensibly linear survival (i.e., curvature not significant in comparison with the errors of the data), the equation

$$N = N_0 (1 - L_s t) \quad \text{I}$$

was used, otherwise,

$$N = N_0 (1 - L_s t) (1 - L_e t) \quad \text{II}$$

Here

$t$  = time (days) from transfusion

$N$  = donor cell count (millions/mm<sup>3</sup>) at time  $t$

$N_0$  = donor cell count at  $t = 0$

$L_s$  = rate of loss of transfused cells by the normal ageing process (proportion of  $N_0$  lost per day)

$L_e$  = a measure of the rate of loss of transfused cells by "extrinsic" processes of destruction

The genesis of these equations is given by Callender, Powell, and Witts<sup>5,6</sup>, the second is an approximation to a more complex form, valid when the curvature is not great. Equation II becomes I when  $L_e$  is zero.

In Table I are set forth the values of the parameters  $L_s$  and  $L_e$  so obtained, and from each pair are derived three other quantities descriptive of the corresponding survival curve, viz

The average time of survival of the transfused cells,  
 $\bar{t}$

$$\bar{t} \simeq 1/2L_s - L_e/6L_s^2$$

The end point of the curve,  $\tau_a$  (days)

$$\tau_a = 1/L_s$$

The proportion of transfused cells lost to "extrinsic" processes of destruction,  $F_e$

$$F_e \simeq L_e \bar{t}$$

Donor A H was exceptional in that the rate of destruction of her cells was more rapid than usual, while still remaining linear. This has been found previously only in pathologic conditions of the recipient (Brown and co-workers<sup>7</sup>), but as already mentioned, the data in this experiment were not entirely satisfactory. The other cases are within the range expected for normal subjects.

The law of survival of sickle cell anemia cells is widely different from the normal. In the four cases we have investigated, the curves obtained were very uniform in character, consisting of (1) a sharp fall in the number of donor cells present for the first few days, followed by a transition to (2) a much slower and nearly linear fall to zero. The average life of the transfused cells,  $\bar{t}$ , was short and the maximum time of survival,  $\tau_a$ , was also reduced. Both quantities differed considerably from case to case. In Table II the values of  $\bar{t}$  and  $\tau_a$  have been calculated from the equation (VI) developed below and fitted to the data, it should be noted that  $\bar{t}$  is not greatly dependent on the form of equation adopted—a good approximation can be obtained directly from the data. The values of the  $\tau_a$  are rather less certain, but if some of the transfused cells did in fact survive e.g. for the normal time, their number was too small to measure.

Other symbols see text

The evidence suggests that the red cells' environment is normal in sickle cell anemia, and so the transfused cells should behave as they would have done if they had remained in the donor's circulation. This is further supported by an experiment in which both donor and recipient were suffering from the anemia (L B to G P, Table II). The relation given by Callender and associates<sup>5</sup> between the survival of transfused cells and the life span as measured from "birth" may, therefore, be applied. If the chance that a cell will live for a time equal to or greater than  $\tau$  is  $\varphi(\tau)$ , then

$$\varphi(\tau) = - \frac{N_1}{n} \left\{ \frac{d}{dt} \psi(t) \right\} \Big|_{t = \tau} \quad \text{--- --- --- --- --- III}$$

where  $\psi(t) = N/N_0$  so that  $\psi(0) = 1$ ,  $N_1$  is the donor's red cell count,  $n$  is the rate of production of his cells per unit volume of blood, and  $N_1/n$  is their true average life. This involves, *inter alia*, the dangerous assumption that  $n$  is reasonably constant for some time before the blood is drawn, but one cannot proceed

Fig 8—(a) An idealised form of the survival curve of transfused sickle cells. (b) and (c) Possible forms of  $\varphi(\tau)$  the chance that a cell will live for a time  $\tau$  from its release into the blood stream

without it, and it has some support from the great similarity of all the survival curves in this group, if  $n$  has been widely variable, the similarity would have been a most improbable occurrence. Equation III asserts that, apart from a constant factor,  $\varphi(\tau)$  is the derived curve of  $\psi(t)$ . So if  $\psi(t)$  is of the form shown in Fig 8,a (which is an idealised and sharpened version of the sickle cell survival curve) then  $\varphi(\tau)$  is as shown in Fig 8,b. Actually, however, because of its high slope and because the first few counts are usually erratic, the first section of the curve is so poorly determined that  $\varphi(\tau)$  might equally be of the form of Fig 8,c. We shall in fact assume that the latter form holds, it may be written as the sum of a constant and a variable term. The latter we take for convenience to be exponential, and write

$$\left. \begin{aligned} \varphi(\tau) &= F + (1 - F) \exp(-L_e \tau), & \tau < \tau_a \\ &= 0, & \tau > \tau_a \end{aligned} \right\} \quad \text{--- --- --- --- --- IV}$$

where  $\exp(-L_e \tau)$  is to be understood as a gross approximation to some function, initially 1, which falls to a small value in a time of the order of  $1/L_e$ .  $\varphi(\tau)$  then

contains three parameters,  $L_e$ ,  $L_c$  and  $\tau_a$ , and so  $N$  which is an integral of  $\varphi(\tau)$ , contains four, a hyperbolic  $\psi$  like Fig 8,a would require five in  $N$

It is important to distinguish the situation here represented by equation IV from the one in which the cells are all equally subject to a nonselective random destructive process as well as a process of certain destruction if they reach the age  $\tau_a$ . For then

$$\varphi(\tau) = \left. \begin{aligned} &\exp(-L_e\tau) && \tau < \tau_a \\ &= 0, && \tau > \tau_a \end{aligned} \right\}$$

$$\text{and hence } \psi(t) = N/N_0 = \frac{\exp(-L_e t) - \exp(-L_e \tau_a)}{1 - \exp(-L_e \tau_a)} \quad \text{V}$$

(This is the exact form of equation II)

$$\frac{d\psi}{dt} = \psi'(t) = - \frac{L_e \exp(-L_e t)}{1 - \exp(-L_e \tau_a)}$$

Now if  $L_e$  is large,  $\psi'(0)$  is large and  $\exp(-L_e \tau_a)$  is very small as they are in transfusions from patients with sickle cell anemia but the  $\psi(t)$  of equation V approaches 0 closely long before  $t = \tau_a$  and  $\psi'(\tau_a)$  is also very small. Therefore the uniform slope of the last portion of the sickle cell anemia survival curve cannot be accounted for by the operation of a highly active, constant, nonselective hemolysis.

We return then to equation IV. It admits of two simple interpretations.

(a) All the red cells have a potential life span  $\tau_a$ . This is less than the normal value and differs from case to case. But in addition they have some inherent deficiency which is gradually corrected as their age increases, many are as a consequence destroyed at an early age, but some survive to attain the age  $\tau_a$ .  $F$  is the fraction which do so survive and  $L_e$  is a measure of the rate of destruction of those which do not.

(b) The red cells leaving the marrow of the donor are of variable quality. A fraction  $F$  live for the same time  $\tau_a$  and after transfusion give rise to the linear tail of the survival curve,  $1 - F$  are more labile and are more or less rapidly destroyed in a time whose average value is of the order of  $1/L_e$ .

The second of these interpretations is the more likely, especially as the red cell cannot be regarded as a living organism. The existence of a small component of random cell destruction, normal in women, has here been neglected. The data are in any case insufficient to allow of its separate estimation.

In order to obtain an equation suitable for fitting to the survival data of sickle cell anemia cells, we integrate IV and find

$$N = \alpha + \beta t + \gamma \exp(-L_e t) \quad \text{VI}$$

where approximately

$$\begin{aligned} \alpha &= N_0 \frac{F}{F + (1 - F)/L_e \tau_a} \\ \beta &= N_0 \frac{F}{F + (1 - F)/L_e \tau_a} \\ \gamma &= N_0 \frac{(1 - F)/L_e \tau_a}{F + (1 - F)/L_e \tau_a} \\ \alpha + \gamma &= N_0 \end{aligned}$$

(In these expressions terms containing the factor  $\exp(-L_c\tau_a)$  have been suppressed since in our application  $L_c\tau_a$  is never less than 5 and  $\exp(-5) = 0.007$  only) The results of the fitting are given in Table II. The goodness of fit is satisfactory, and from the values of  $\alpha$ ,  $\beta$ ,  $\gamma$  and  $L_c$  have been calculated the same three quantities as before

The average time of survival of the transfused cells,  $\bar{t}$

$$\bar{t} = \frac{\gamma/L_c - \alpha^2/2\beta}{\alpha + \gamma}$$

The end point of the curve,  $\tau_a$

$$\tau_a = -\alpha/\beta$$

The proportion of transfused cells of abnormally short life, those we have represented as destroyed by an exponential hemolytic process,  $F_c$

$$F_c = \gamma/(\alpha + \gamma)$$

$F_c$  is also the proportion of cells of the short-lived type in the donor's circulation,  $1 - F_c$  the proportion surviving to age  $\tau_a$

In this short series no well-defined correlation of survival time with the blood picture of the donors is evident

There is however an interesting regularity in the values of  $F_c$ , they range only from 0.65 to 0.70, and so to the present degree of accuracy  $F_c$  can be regarded as constant. With so few examples to draw from it would be unsafe to read any physiologic significance into this, rather it suggests that only two and not three variable parameters are necessary in the expression of  $\varphi$ , three and not four in  $N$ . Equations IV and VI are thus perhaps unnecessarily complex, but we have so far no real guidance as to how they should be modified.

#### DISCUSSION

These results indicate clearly that the increased hemolysis in sickle cell anemia is a function of the abnormal erythrocyte itself, there is no evidence that hormonal or erythrophagic factors are directly responsible. Similar conclusions have been reached by Singer, King, Robin, and Jefferson in independently conducted studies<sup>10</sup>. It seems likely that the abnormal shape of the sickled cell makes it less able to tolerate the trauma of circulation. Compatible with this explanation is the *in vitro* demonstration by Diggs and Bibb<sup>11</sup> that cells from patients with sickle cell anemia, when shaken in an atmosphere of carbon dioxide, hemolyse more readily than do normal cells so treated. Shen, Castle, and Fleming<sup>12</sup> obtained similar results with blood from one patient with sickle cell disease. It is not entirely clear whether this patient had the trait only or the active disease, presumably the former as the hematocrit was 44 per cent.

One of us (J. N.),<sup>13</sup> in an extensive study of the susceptibility of red cells to mechanical trauma, has repeatedly confirmed this finding of decreased resistance of sickled cells, and has shown, furthermore, that such cells are normally resistant when fully oxygenated and in the form of biconcave discs.

One would expect, therefore, that if intravascular sickling could be reduced, the rate at which cells from patients with sickle cell anemia are destroyed would

be decreased. The earlier observations of Reinhard and co workers<sup>8</sup> showing with the Sherman technique that intravascular sickling is decreased when patients breathe 70 to 80 per cent oxygen were again confirmed in the experiments described herein. It is not surprising, therefore, that erythrocytes transfused from a patient with sickle cell anemia seemed to survive longer in one of the subjects who breathed high concentrations of oxygen. We are unable to correlate this observation with the fact that intravascular hemolysis as measured by total urobilinogen excretion did not seem to be decreased in patients with sickle cell anemia during periods of oxygen inhalation.<sup>8</sup> The urobilinogen methods may not have been sensitive enough to detect the relatively slight decrease in rate of destruction.

Previous workers have suggested that ease of sickling is a function of the age of the cells because they observed that nucleated red cells and reticulocytes appear to sickle less readily than do other erythrocytes.<sup>11, 14, 15</sup> However, if sickling is mainly a function of age the life expectancy of all cells in sickle cell anemia should be reduced. Instead the graphs of survival of the transfused sickle cell anemia erythrocytes show that there is a tendency for a proportion of the cells to survive almost normally.

Case 3 of Singer and associates<sup>10</sup> in which blood from two donors with sickle cell anemia was given to one subject with sickle cell trait shows a similar type of graph. This was interpreted as being due to admixture of blood from a severe and a milder form of the anemia. Our data suggest an alternative interpretation, namely that while most of the cells are constitutionally more susceptible to sickling and remain so until they are prematurely destroyed others are born more resistant and remain so throughout their existence. According to this hypothesis sickle cell trait might be regarded as the extreme example of a state in which all the cells are constitutionally more resistant to sickling.

There are other reasons for thinking that the difference between sickle cell anemia and the trait is qualitative. (1) In patients with the trait there are fewer circulating sickled forms<sup>3</sup> even though most of the cells must be older than in sickle cell anemia. (2) Transfused trait cells survive normally in spite of their average greater age and their ability to sickle. (3) When trait cells are completely sickled by exposure to CO and then subjected to mechanical trauma they are much less readily destroyed than are anemic cells under similar circumstances.<sup>13</sup> It is difficult to interpret the experiment in which no accelerated destruction of trait cells occurred when they were transfused into a young boy with chronic cyanosis from congenital heart disease. That result may be another indication of the resistance of trait cells to sickling and to abnormal hemolysis. On the other hand the oxygen tension may have to be lowered to 18 mm mercury<sup>3</sup> before sickling occurs and it may well be that such low tensions were never reached in this boy's circulation in spite of his cyanosis.

If the difference between the two types of sickle cell disease is caused by a qualitative difference in the erythrocyte structure, it is easier to understand why no entirely satisfactory, clear cut examples of forms intermediate between the two have been described. In these studies a search was made for evidence that there might be a continuous spectrum in the behaviour of cells transfused from subjects with sickle cell disease ranging from the severe anemia through milder

forms to the trait With the one exception provided by an unsatisfactory experiment (subject A H, Table I), however, there was a sharp distinction between the survival graphs of cells transfused from patients with the anemia and those with the trait

#### SUMMARY AND CONCLUSIONS

The Ashby technique of differential agglutination has been used to study the survival of transfused cells in relation to sickle cell disease

Normal red blood cells transfused to three patients with sickle cell anemia showed a normal survival time

Red cells from patients with sickle cell anemia transfused to normal recipient subjects and others with sickle cell anemia showed a shortened average time of survival

Red cells from healthy donors with the sickle cell trait transfused to normal recipient subjects and a patient with sickle cell anemia showed a normal survival time

Oxygen inhalation reduced the rate of destruction of transfused sickle cell anemia cells in one patient with sickle cell anemia Such an effect was not seen in one normal recipient The survival time of sickle trait cells given to a boy with chronic cyanosis was normal

The findings indicate that the defect in sickle cell anemia is inherent in the red blood cell There is evidence to suggest that sickling is not, as has been thought, a function of age of the cell but that the cells in sickle cell anemia vary constitutionally in their liability to sickle It is suggested that the difference between the anemia and the trait is qualitative and not simply one of degree.

# USE OF THYMOL TURBIDITY AS LIPID ABSORPTION TEST

## EXPERIENCES WITH THYMOL TURBIDITY AND ZINC SULFATE TURBIDITY TESTS UNDER PHYSIOLOGIC AND PATHOLOGIC CONDITIONS

HANS POPP, M.D., PH.D. FREDERICK STEIGMANN, M.S. M.D.,  
HATTIE DYNIEWICZ, PH.D., AND ALVIN DUBIN, M.S.  
CHICAGO, ILL.

THYMOL turbidity<sup>1</sup> results from an interplay of several factors. These are (a) reduction of serum albumin,<sup>2</sup> (b) increase of either the gamma<sup>1</sup><sup>3</sup> or beta<sup>4</sup> globulin fraction or more probably of lipid protein complexes electrophoretically migrating with the latter and/or (c) increase of lipids, especially phospholipids.<sup>5</sup> An incidental observation that the thymol turbidity increases significantly in normal dogs after meals suggested that the influence of ingested lipids or substances promoting lipid absorption upon thymol turbidity be investigated in normal subjects and in patients with various diseases. For comparison, the effect of lipid intake upon the blood total lipids, phospholipids and zinc sulfate turbidity was studied. The latter was recently described by Kunkel<sup>6</sup> as an index of serum gamma globulin concentration.

This study was planned to supply information as to whether the thymol turbidity could be adopted as a test for lipid absorption. It also provided additional observations as to the differential diagnostic value of thymol and zinc sulfate turbidity in liver disease.

### MATERIAL AND METHOD

Blood specimens were obtained from 471 patients. Some of them suffered from liver diseases as confirmed by a series of liver function tests and/or liver biopsies. Others had various other internal diseases. A third group was admitted to the hospital for conditions not internal in nature, for example fractures, simple hernia, small lacerations (control patients). On all specimens, the thymol turbidity was determined according to MacLagan.<sup>1</sup> It was expressed in units derived from a curve calibrated with barium sulfate.<sup>7</sup> In 114 cases, determination was made of the turbidity which developed after dilution of the serum with a buffered 2.4 mg. per cent zinc sulfate solution and in sixty cases after dilution with either the phenolbarbital buffer or distilled water alone. In five patients, determination was also made of the total serum lipids according to Boyd<sup>8</sup> and of the phospholipids as phosphates according to Fiske and Subbarow<sup>9</sup> after extraction according to Bloor.<sup>10</sup> The determination of the thymol turbidity was repeated in 165 cases, three and six hours following the ingestion of various lipids and/or 6 Gm. of choline hydrochloride in elixir form.\* In some patients the test was performed after the intake of different types of lipids. The turbidity produced by serum dilution with zinc sulfate, distilled water or a buffer solution was also measured in a smaller number of cases after lipid intake. The repeat determinations were made three and six hours after lipid intake because of previous experiences with vitamin A tolerance curves.<sup>11</sup>

In confirmation of this, the maximal elevation of the thymol turbidity was found between three and six hours in five experiments in which blood was drawn hourly for six hours. The difference between the fasting level and the highest level after ingestion of lipids (maximal rise) was expressed as absolute difference or in per cent of the prelevel, respectively. For the analysis of the prevalue in the different clinical conditions, only the first determination on each patient was utilized. For determination of statistically significant differences the T value was determined according to the following formula:

$$t = \frac{\bar{x} - \bar{x}'}{s} \sqrt{\frac{(N_1 - 1)(N_2 - 1)}{N_1 + N_2 - 2}}$$

$\bar{x}$  = mean of one sample  
 $\bar{x}'$  = mean of second sample  
 $N_1$  = number in first sample  
 $N_2$  = number in second sample  
 $s$  = pooled standard deviation

A T value above 2.5 indicated a statistically significant difference.

In ten cases the thymol turbidity was determined before and after lipid intake on sera (1 ml) extracted once or several times with 5 ml of petrol ether or ethyl ether, similarly on sera (1 ml) to which 20, 40, or 100 mg of heparin were added, respectively, and on plasma from heparinized blood.

## RESULTS

*Thymol and Zinc Sulfate Turbidity in Various Pathologic Conditions*—The thymol turbidity varied in control patients from 0.5 to 6.9 units with an average of 2.1 (Table I). In only four instances was it above 4 units, which is usually considered as the upper limit of the normal. The average was slightly higher in patients with nephritis, heart disease, cachexia, infections and malignant tumors other than those of the biliary tract. In the latter three groups, the range extended occasionally into highly abnormal values. The average in gastrointestinal diseases was in the pathologic range, however, the statistical difference from the normal was not significant. Nonjaundiced patients with fatty livers (established by liver biopsy) had a normal turbidity. The average turbidity in acute hepatitis with jaundice was markedly elevated, the difference being statistically impressive. In only 7.9 per cent of the 126 cases of hepatitis was the turbidity below 4 units, however, some of these patients had almost completely recovered. The average in the nonicteric patients with cirrhosis was somewhat lower than in those with acute hepatitis though the difference from the norm was still statistically significant. In only 20.5 per cent of the nonicteric patients with cirrhosis was the turbidity below 4 units. The results in patients with cirrhosis with jaundice simulated those of acute hepatitis, only 12.9 per cent had a turbidity below 4 units. The cases of cirrhosis (with or without jaundice) which had a normal thymol turbidity were not necessarily less active than those with a high turbidity. In the biliary type of hepatitis produced by prolonged extrahepatic biliary obstruction, the average was only slightly elevated. Nevertheless, the difference from the normal was just statistically significant, a turbidity above 7 units was found in only 11.5 per cent. In the purulent type of hepatitis in which extrahepatic biliary obstruction was complicated by bacterial infection of the portal triads, the average turbidity was definitely above normal. The statistical difference from the normal was quite significant. In this group of seventeen cases, only in two was the turbidity normal and in five it was below 7 units.

TABLE I AVERAGE LEVEL, RANGE AND STATISTICAL SIGNIFICANCE OF ABSTENTION FROM NORMAL OF THYMOL AND ZINC SULFATE TURBIDITY IN HOSPITAL CONTROLS AND PATIENTS WITH VARIOUS DISEASES

DIAGNOSIS	THYMOL TURBIDITY				ZINC SULFATE TURBIDITY

Cirrhosis without jaundice	39	6.3	1.2-17.4	4.1	12	14.9	5.0-25.2	2.2
Cirrhosis with jaundice	91	10.1	1.0-6.8	9.7	15	21.2	2.4-59.2	4.5
Biliary hepatitis	69	4.0	0.0-14.0	2.8	13	1.6	2.7-17.0	0.2
Purulent hepatitis	17	13.0	3.0-25.0	7.8	2	4.0	4.0-5.0	0.2

The zinc sulfate turbidity revealed in normal subjects an average of 8 units, it was above 10 units in five out of thirty three cases. Slightly higher values were obtained in patients with heart disease. An average of about 15 units was obtained in infections, cachexia, gastrointestinal diseases, malignant tumors and cirrhosis without jaundice. In patients with acute hepatitis and especially in cirrhosis with jaundice the average elevation was even higher. This elevation was statistically significant. In 20 per cent of patients with acute hepatitis and in one third of those with cirrhosis and jaundice the zinc sulfate turbidity was below 10 units. In both forms of secondary hepatitis (biliary and purulent) the average turbidity was normal being above 10 units in only 13.3 per cent of such cases.

*Influence of Intake of Various Lipids Upon Thymol Turbidity*—After the intake of almost every type of lipid, the thymol turbidity rose moderately in control patients, but only slightly in patients with liver disease (Table II). The zinc sulfate turbidity rose also but far less than the thymol turbidity when expressed in percentage of the prevale. Thymol flocculation was not produced by administration of any of the lipids. The highest rise was encountered after intake of 50 Gm of butter. Some orientation experiments showed that the addition of 6 Gm of choline to 50 Gm of butter produced an even higher rise of the thymol turbidity than butter alone. Therefore the effect of butter, butter with choline, and choline alone was compared in another series of patients with various diseases (Table III). Butter and choline produced usually a greater elevation of the thymol turbidity than butter alone. However this

did not occur in all cases. Choline alone elevated the thymol turbidity significantly less than butter with choline or butter alone. The response of the thymol turbidity to butter and choline intake, alone or together, was far less marked in patients with liver disease.

TABLE II INFLUENCE OF ADMINISTRATION OF VARIOUS LIPIDS UPON THE THYMOL TURBIDITY

SUBSTANCE	AMOUNT	HOSPITAL CONTROL PATIENTS			PATIENTS WITH LIVER DISEASE

*Influence of Intake of Butter and Choline Upon Blood Lipids and Turbidity Tests*—The thymol turbidity, phospholipids and total lipids rose in three control patients, the maximum elevation occurring three hours after the intake (Fig. 1). The zinc sulfate turbidity rose to a lesser degree. The slope of the rise was the steepest in the thymol turbidity, less in the serum phospholipids, and still less in the total lipids. All four factors rose insignificantly in the two patients with cirrhosis. In one control patient, the difference between the response to butter and choline, on one hand, and butter or choline alone, on the other hand, (previously described for the thymol turbidity) was mirrored by

the phospholipids, but not by the total lipids or the zinc sulfate turbidity (Table IV) In the two patients with cirrhosis (only one recorded in Table IV) the rise in all instances was insignificant and did not permit comparison

Fig 1—Response of thymol turbidity zinc sulfate turbidity serum lipid phosphorus and plasma total lipids to the intake of 50 Gm of butter and 6 Gm of choline

TABLE IV COMPARISON OF THE RISE OF THYMOL TURBIDITY, ZINC SULFATE TURBIDITY, SERUM LIPID PHOSPHORUS AND TOTAL LIPIDS AFTER ADMINISTRATION OF 50 GM BUTTER TOGETHER WITH 6 GM CHOLINE AND AFTER BUTTER OF CHOLINE ALONE IN A HOSPITAL CONTROL AND IN A PATIENT WITH CIRRHOSIS

*Response of Thymol and Zinc Sulfate Turbidities to the Simultaneous Intake of 50 Gm of Butter and 6 Gm of Choline in Various Pathologic Conditions*—The rise of the thymol turbidity in control patients was on the average 3.1 units or 237.4 per cent. The rise was below 1 unit in only three out of thirty-nine instances (Table V). The same response was found in neurologic conditions and in a few cases of nephritis. The rise in thymol turbidity was

significantly less in patients with infections, carcinomas (other than those involving the biliary tract) and cardiac or wasting diseases, the average being around 1 unit. The smallest response was noted in gastrointestinal diseases in which the turbidity rise was only about 0.6 unit. The response was also depressed to a statistically significant degree in liver diseases with the exception of acute hepatitis. If expressed in per cent, the lack of rise was especially marked in liver diseases in view of their elevated prevalues. In patients with acute hepatitis, who usually had a high prevalue, the absolute rise was nearly normal, but the percentage rise was almost the lowest recorded. The rise was slight, whether comparisons were made in units or percentages, in cases of cirrhosis with jaundice and in obstructive jaundice. This was so despite frequent elevation of the prevalues. In general, a rise below 1.5 units suggested an aberration from the normal. Elevations of less than 1.0 unit pointed to a pathologic condition. As a general trend, low fasting levels of the thymol turbidity were associated with a significant response to administration of butter and choline. Patients with high fasting levels showed, as a rule, little response (Fig. 2). An exception to this was noted in acute hepatitis in which an almost normal response occurred in face of a high fasting turbidity. Another exception was seen in gastrointestinal disturbances in which both fasting level and response were low.

The zinc sulfate turbidity responded similarly to the thymol turbidity, but its rise was less marked whether in units or in per cent of the preliminary value. The low turbidity readings of serum dilutions with either distilled water or sodium barbitol-barbitol buffer without thymol were only slightly (not over 0.2 unit) if at all influenced by lipid intake.

Fig 2—Plot of the thymol turbidity before and after administration with the maximal rise following administration of 50 Gm butter and 6 Gm choline in hospital controls and patients suffering from various diseases

Fig 3—Influence of adding of heparin to the serum or extracting it with ethyl ether upon the thymol turbidity in a hospital control and a patient with acute hepatitis before and after administration of 50 Gm butter and 6 Gm choline

*Influence of Lipid Solvents Upon Thymol Turbidity*—As observed in at least twenty-five cases of each group, the thymol turbidity, normal or elevated due to either disease or intake of butter and choline, was not altered by extraction of the serum with petrol ether, but was markedly reduced by extraction with ethyl ether (Fig 3). The thymol turbidity was reduced in serum to which heparin was added as well as in plasma from heparinized blood independently of pathologic or postprandial elevation. This reduction was augmented by increasing the amount of heparin used or repeating the ethyl ether extraction.

#### DISCUSSION

The diagnostic value of the thymol turbidity test, reported by many investigators,<sup>1, 12, 20</sup> has been confirmed in this study. The turbidity was occasionally elevated in various conditions with possible secondary involvement of the liver, for example general infections, malignant tumors and gastrointestinal diseases, however, it was regularly and markedly elevated in acute hepatitis. It remained normal in patients with fatty livers. In cirrhosis with jaundice the turbidity was usually slightly lower, and in cirrhosis without jaundice, it was markedly lower than in acute hepatitis. In contrast, extrahepatic biliary obstruction, even of prolonged duration, usually revealed a normal turbidity. This difference was especially noticeable if the border line was drawn at 7 units. However, if a bacterial infection involved the portal triads, for example cholangitis, complicated extrahepatic biliary obstruction (purulent hepatitis<sup>17</sup>), the thymol turbidity became markedly elevated, as a rule, to over 7 units. The difference between elevated thymol turbidity in primary hepatitis or cirrhosis and normal turbidity in extrahepatic biliary obstruction even with liver damage is of practical importance.<sup>21</sup> This difference holds true only in the absence of bacterial infection of the portal triads.<sup>16</sup>

The demonstrated difference in the results of the thymol turbidity test in various conditions is apparent in the mean or in a statistical evaluation of a larger number of cases but may not necessarily hold true for individual patients. Thus, a normal thymol turbidity may occasionally be found in hepatitis or cirrhosis with marked jaundice when other hepatic tests are abnormal. Conversely, the thymol turbidity may be elevated in extrahepatic jaundice and even in diseases not primarily hepatic such as rheumatoid arthritis.<sup>24, 25</sup>

Elevation of the zinc sulfate turbidity was found not only in hepatic diseases but to almost the same degree in other inflammatory and neoplastic conditions with little or no liver damage. In contrast, it was normal in the cases of extrahepatic biliary obstruction. This latter observation, if confirmed on a large number of cases, would make this test of great value in the differentiation between extrahepatic biliary obstruction and primary hepatitis and cirrhosis. The significance of the zinc sulfate turbidity test thus appears to lie in its failure to rise in extrahepatic jaundice. The zinc sulfate turbidity was especially high in cirrhosis. As a rule, markedly elevated zinc sulfate turbidity in face of only moderately elevated thymol turbidity suggests cirrhosis. On the other hand, high thymol turbidity with moderately elevated zinc sulfate turbidity speaks for an acute hepatitis.

The transient rise of the thymol turbidity after lipid intake (especially after butter and choline) may have diagnostic significance because it parallels the rise of the blood total lipids and especially of the phospholipids. That the postprandial rise of the thymol turbidity is due to serum phospholipid elevation is also indicated by the high phospholipid concentration of the precipitate produced by adding thymol to serum. This hypothesis is also supported by the observation that choline, which is essential in lecithin formation, may enhance the effect of butter ingestion upon the thymol turbidity and the serum phospholipid level. Furthermore, the administration of choline alone increases the thymol turbidity.

The rise of the thymol turbidity after butter alone may result from a combination of fats with phospholipids during absorption,<sup>4,10</sup> although such a combination is still controversial.<sup>2</sup> Increase of the butter effect by choline could be ascribed to a role of choline in the fat transport through the intestinal wall,<sup>6,27</sup> similar to the function of choline in fat mobilization from the liver.<sup>28,29</sup>

The elevation of the thymol turbidity induced by fat ingestion and the spontaneous elevation in pathologic conditions like acute hepatitis are equally lowered by ethyl ether but not by petrol ether extraction of the serum.<sup>6</sup> Both elevations are equally depressed *in vitro* by heparin which is known to abolish visible lipemia, at least *in vivo*.<sup>30,31</sup> That does not necessarily imply that the increase in the thymol turbidity in liver diseases is primarily due to a lipid factor. Thus, Kunkel and Hoagland<sup>2</sup> have shown that at least in some stages of acute hepatitis the thymol turbidity elevation depends primarily on protein changes.

The response of the thymol turbidity to the administration of butter and choline can be considered as an index of intestinal lipid and most probably phospholipid absorption. The rise is only slight in many conditions in which a disturbance of fat absorption can be expected as in gastrointestinal or in severe wasting diseases. Poor response may be found in obstructive jaundice or in hepatic diseases, for example cirrhosis, which have a high spontaneous thymol turbidity. Such a minimal rise is not necessarily caused by liver damage as such, in view of the almost normal response in infectious hepatitis. It is more likely due to associated gastrointestinal disturbances. The response of the thymol turbidity to lipid intake represents thus a technically simple test for intestinal lipid absorption which may be of diagnostic value.

#### SUMMARY

In confirmation of previous reports, the thymol turbidity test was found elevated in acute hepatitis, less so in cirrhosis with and without jaundice. It was normal in patients with fatty livers without jaundice, slightly elevated in obstructive jaundice without infection of the biliary tract but elevated when bacterial infection was present. Occasionally, elevation was found in diseases without apparent liver involvement while in rare instances of even severe primary liver cell damage the turbidity was normal.

The zinc sulfate turbidity was found elevated in liver diseases and in inflammatory or malignant conditions in general but was normal in cases of extrahepatic obstructive jaundice. Therefore, a low zinc sulfate turbidity is of great diagnostic importance. The ratio between thymol and zinc sulfate turbidity is of practical significance in the differentiation of acute hepatitis and cirrhosis.

Administration of various lipids raised the thymol turbidity. For this purpose, 50 Gm butter given together with 6 Gm choline are especially efficient. The rise of the thymol turbidity was parallel with that of the serum phospholipids, but less so with that of the total plasma lipids and the zinc sulfate turbidity. Butter or choline alone usually produced a less marked rise than butter and choline together.

The spontaneous elevation of the thymol turbidity produced by pathologic conditions as well as the rise caused by the intake of lipids is equally reduced *in vitro* by adding heparin to the serum or by extracting serum with ether but not with petrol ether. The rise in the thymol turbidity after the ingestion of fat was markedly depressed in gastrointestinal diseases, obstructive jaundice and cirrhosis. The depression in wasting diseases was of lesser degree. In acute infectious hepatitis the postprandial rise was almost normal. The response of the thymol turbidity to the intake of butter and choline may serve as a simple clinical test of intestinal absorption of fat.

# THE BOUND GLUCOSAMINE OF SERUM MUCOID IN DIABETES MELLITUS, FLUCTUATIONS OBSERVED UNDER THE INFLUENCE OF INSULIN

HENRY R. JACOBS, M.D.  
EVANSTON, ILL.

MANY authors have speculated upon the metabolic disorder associated with the carbohydrate defect in diabetes mellitus. This paper presents data obtained in a study of the concentration of glucosamine in the blood of diabetic and other patients.

Glucosamine is thought at present to occur in blood in the form of a polysaccharide composed of acetylglucosamine, mannose and galactose, bound to a protein molecule of the plasma, the whole complex is termed a mucoid, or a seromucoid<sup>1</sup>. Ordinary methods of precipitating plasma proteins, as by salting out or by treating with alcohol, coprecipitate the seromucoids with the albumin and globulin. A useful way of separating them is to acidify the plasma slightly and then to heat it briefly<sup>1</sup>; the albumins and globulins coagulate promptly, leaving the serum mucoids in the clear liquid.

## METHOD

A few simple preliminary studies sufficed to devise a process for routine preparation of blood samples for this preliminary survey. The following procedure was used. One milliliter of ovalated plasma was mixed with 3 ml of 0.01N HCl in a 15 ml conical centrifuge tube. The tube was placed in a boiling water bath for three to four minutes while its contents were kept in motion. Coagulation occurred rapidly. The tube was then cooled and centrifuged. The supernate was removed and placed in a 5 ml glass ampul, and the ampul sealed with a blowlamp. The sealed ampul was heated in a boiling water bath for twenty-four hours to liberate glucosamine from the polysaccharide complex.

Color was produced according to the method of Elson and Morgan,<sup>2</sup> following the additional directions of Palmer, Smyth, and Meyer.<sup>3</sup> The following reagents are required (all should be kept in icebox):

1. Two per cent acetylacetone in 0.5N Na<sub>2</sub>CO<sub>3</sub>. Add 0.2 ml acetylacetone to 10 ml 0.5N Na<sub>2</sub>CO<sub>3</sub>, and dissolve by shaking. Prepare fresh every day or two.

2. *p*-Dimethylaminobenzaldehyde reagent. The substance must be purified before use.<sup>2, 3</sup> Dissolve 0.8 Gm in 30 ml aldehyde-free alcohol and add 30 ml concentrated HCl.

3. Aldehyde-free alcohol. This is prepared by distillation of absolute alcohol after treatment with Ag<sub>2</sub>O and sodium hydroxide,<sup>3</sup> and diluting to make 95 per cent.

4. Glucosamine standard. Twice recrystallized glucosamine HCl is dissolved in water saturated with chloroform to make 20 mg per 100 milliliters.

The sealed ampul was opened after twenty-four hours of heating and the contents were filtered. One milliliter of the filtrate was placed in a test tube marked at 10 milliliters. One milliliter of the acetylacetone reagent was then added, and the sides of the tube were washed down with 1 ml of water. A standard was set up in the same manner, using 1 ml of the standard solution. A blank was made using 1 ml of water, but otherwise treated exactly as the test and standard mixtures. The tubes were heated in a boiling water bath for fifteen minutes, then cooled. Approximately 2 ml of aldehyde-free alcohol were added to each tube, following

Received for publication Sept. 14, 1948.

which 3 ml of *p* dimethylaminobenzaldehyde reagent were added to each. Then aldehyde free alcohol was added to each tube to the 10 ml mark, the contents of each were mixed thoroughly and all were set aside for forty five minutes for the colors to develop and for bubbling to cease.

Color comparisons were made in a Coleman spectrophotometer. A wave length setting of .35 was found to be most sensitive to the color, and was therefore used throughout. The blank solution was first employed to establish the blank value, after which the standard and the test solutions were measured in the machine. The glucosamine content of the test sample was read from a calibration curve previously established for the instrument and for the method through a range of known glucosamine concentrations from 5 to 100 mg per cent. The standard solution served to verify this curve each time in the neighborhood of 20 mg per cent. Whenever the test sample showed unusually high values, it was customary to repeat the determination after diluting the original filtrate enough to bring the concentration well below 40 mg per cent.

In passing it should be mentioned that the method employed was designed to measure the glucosamine that is easily separable hence the values found represent only this portion. More drastic methods of hydrolysis and use of whole plasma will doubtless give higher values for "total" glucosamine.

Fig 1—A scatter diagram to show the correlation between blood glucose and blood glucosamine in nondiabetic and in diabetic subjects. This diagram presents the data given in the tables.

## RESULTS

Three hundred and seventy eight determinations were made upon 250 subjects. It was soon obvious that plasma glucosamine followed the blood sugar level and that the findings of greatest interest would be made upon diabetic blood. In the tables the data are separated into two categories: diabetic and nondiabetic. The examples offered were selected because blood sugar determinations were made with the glucosamine studies; those left out had no blood sugar determinations, but the glucosamine levels were not unique in any way. The values offered in the tables appear in the scatter diagram (Fig 1).

TABLE I PLASMA GLUCOSAMINE CONTENT AND BLOOD SUGAR LEVELS IN NONDIABETIC SUBJECTS

SEX AND AGE		GLUCOSAMINE (MG %)	GLUCOSE (MG %)	CLINICAL STATE
<i>0.9 mg per cent</i>				
M	46	2.7	83	Cholelithiasis, icteric index 7.0

		35.2	124	2 30 P M
		56.2	288	4 30 P M

The nondiabetic group was composed of 151 individuals, and their glucosamine levels ranged through the following concentrations

GLUCOSAMINE LEVEL	NUMBER OF INDIVIDUALS
17 to 10 mg per cent	29
11.0 to 20.0	73
21.0 to 26.0	37
27.0 and above	12

Although it is not possible to establish a "normal" range of glucosamine levels from this study because no normal subjects were included it seems likely that normal values by this method will lie in the neighborhood of 15 to 25 mg per cent. The lowest value found was 1.7 mg per cent, the highest among the nondiabetics, 52.8 mg per cent. Perhaps the only observation to be considered at this time is that the level seems to rise with age. Several patients under treatment with sulfadiazine gave levels above the normal, but the disease being treated may have been partly responsible for the effect. The high incidence of neoplasia and of cardiovascular disease in the group having the highest glucosamine levels among the nondiabetic subjects perhaps depends as much upon the advanced age of the subjects as upon their diseases.

The diabetic group (Table II)\* was composed of forty three individuals of which twenty six appear in the table. All were in the Hospital under treatment. Those left out resembled those shown in all essential respects. Two features are noteworthy: glucosamine levels far higher than occur among non-diabetic subjects are frequently encountered, and glucosamine levels parallel blood sugar levels with remarkable consistency. Glucosamine levels above 40 mg per cent are unusual among nondiabetic subjects, yet they are common in diabetic subjects. Levels as high as 90 to 95 mg per cent have been observed.

Fig. —The response of blood glucosamine to insulin in a diabetic subject. The graph shows how both blood glucose and blood glucosamine fall after a dose of insulin in a young diabetic subject (F 17 of Table II). Note also that glucosamine rises with glucose as the insulin effect disappears.

in uncontrolled diabetes. The remarkable parallelism between glucosamine and glucose levels which is evident in Table II is not unvarying, divergences occur frequently enough to indicate that two phenomena are involved. Dissociation is often observed during insulin effect: the fall of glucosamine frequently lags behind the fall of blood sugar.

Glucosamine is obviously responsive to insulin. A single experiment was performed (F 17 in Table II) in which blood sugar and glucosamine were measured every two hours after an adequate dose of insulin had been given. Within four hours the blood sugar fell from 284 to 114 mg per cent, and during that interval glucosamine dropped from 81.6 to 36.0 mg per cent. Four hours later the blood sugar had risen again to 288 mg per cent, and during that time the glucosamine rose to 56.2 mg per cent. The correspondence is shown in the graphs in Fig. 2.

The association of glucosamine level with age of subject mentioned earlier in discussing nondiabetic data is not apparent among diabetic subjects, very high levels are encountered at all ages and so are low levels after insulin. The absence or presence of control of the diabetic state overshadows all other possible effects on the plasma glucosamine level in diabetic subjects.

## DISCUSSION

The experiences described in this paper indicate that the mucopolysaccharide of the mucoid fraction of blood plasma which yields glucosamine after mild acidic hydrolysis is somehow involved in the diabetic defect, and that it responds to insulin in roughly the same manner as glucose itself as far as the direction, speed, and magnitude of the response is concerned. The only earlier report to be found, that of West and co-workers,<sup>4</sup> states that glucosamine in diabetic blood is not elevated. These workers used another and more drastic method of hydrolysis, and they employed whole serum directly.

Nothing is known about why the mucopolysaccharide under discussion should appear in greater amounts in uncontrolled diabetes. Many substances appear in greater amounts under that circumstance, and many of them are responsive to the effect of insulin. A recent general theory of the function of insulin<sup>5</sup> postulates that the glucose anomaly in diabetes is but one manifestation of insulin deficiency, perhaps the phenomenon described in this paper is another.

## SUMMARY

1 A procedure is given by which easily separable serum mucoid glucosamine was studied.

2 Representative data for nondiabetic and for diabetic subjects are offered.

3 Insulin seems to exert a pronounced effect on the level of glucosamine found by the method described.

# DIBUTOLINE AS AN ANTIDOTE FOR DIISOPROPYL FLUOROPHOSPHATE POISONING IN MICE

CLORCE H. BIGGINS, M.D.

LOMA LINDA, CALIF.

THE toxicity of diisopropyl fluorophosphate (DFP), an anticholinesterase agent, has been described by a number of authors. The early reports which established the mode of action and toxicity of DFP are not generally available but are quoted in several published articles. Scholz<sup>1</sup> reported that topical application in the eye could produce death in rabbits which resembled eserine poisoning. McNamara, Koelle, and Gilman, and also, Modell and Krop<sup>2</sup> pointed out that DFP, an anticholinesterase is toxic by a combination of nicotinic and muscarinic actions. No single drug is known which will protect from both of these actions. Atropine provides various degrees of protection against the muscarinic effects of DFP or the closely related dimethyl fluorophosphate in cats, rabbits, and mice.<sup>2, 3, 4</sup> In cats and mice this antidote is moderately effective since the muscarinic action is the dominant one. It is much less effective in the rabbit where the nicotinic effect predominates. These same authors reported that magnesium sulfate counteracts the nicotinic effects of DFP. Salts of calcium, aluminum and gold, according to Modell, also have some "anti nicotinic action." Magnesium sulfate alone seldom prevented death in the animal administered DFP, but when it was combined with atropine the combination gave greater protection than either drug alone. Whereas it was to be expected that the combination of two anticholinesterase agents would increase the toxicity, Koster<sup>5</sup> found that this was not true when physostigmine was administered before DFP. Physostigmine protected from a subsequent lethal dose of DFP. DFP given before physostigmine increased the toxicity of physostigmine. This seemingly paradoxical result was further studied and explained by Koelle<sup>6</sup> who classified nineteen other anticholinesterase agents for their protective action against DFP.

Acetyl beta methylcholine protects mice from inhaled dimethyl fluorophosphate but not from parenteral injections. This protection apparently is due to local action on the respiratory tract which alters the rate of absorption of the inhaled drug.<sup>4</sup>

Seeking a less diastolic cycloplegic agent than atropine for ophthalmologic use, Swan and White<sup>7</sup> synthesized a series of choline esters which have blocking rather than stimulating effects on the parasympathetic system. Dibutoline<sup>8</sup> (dibutyl urethane of dimethyl ethyl  $\beta$  hydroxyethyl ammonium sulfate) was found to be the most suitable compound of the group. The general pharmacology of dibutoline has been studied by Featherstone and White<sup>9</sup> and by Peterson and Peterson<sup>10</sup> who have definitely established the blocking action on the parasympathetic system. Pfeiffer<sup>11</sup> has suggested that the atropine like

From the Department of Physiology, School of Medicine, College of Medical Evangelists.

This work was supported in part by a grant of funds from the Alumni Research Foundation of the College of Medical Evangelists.

The dibutoline and diisopropyl fluorophosphate were obtained through the generosity of Merck and Company, Rahway, N. J.

Received for publication Aug. 20, 1948.

action of dibutoline may be due to a similar umbrella-like spacial arrangement of prosthetic groups in the molecule

The similarity of action of dibutoline to atropine raised the question as to whether dibutoline would have a protective effect against DFP. The present study is an attempt to evaluate dibutoline as an antidote for DFP poisoning.

#### EXPERIMENTAL METHODS

Three groups of mice, averaging 25 grams each, were obtained and used for the study.\* Mice from each of these groups were given intraperitoneal injections of fresh DFP solution in Ringer's solution so prepared that the desired dosage of drug would be contained in 0.5 cc of solution. After the responses of a number of unprotected mice were observed, various dosages of atropine or dibutoline were given to other mice. One minute later these mice were injected with the same dosage of DFP used previously.

Control groups of mice were injected with various doses of dibutoline or atropine alone. When death occurred it was usually within thirty minutes, but any death within one week was assumed to be due to the medication.

#### RESULTS

The sensitivity to DFP varied in the different groups of mice, but each group in itself was quite consistent. In animals of the first group DFP 0.125 mg per animal produced a mortality of 38 per cent. See Table I. When atropine 0.02 mg per animal was administered one minute before the DFP the mortality was reduced to 12 per cent. This same dosage of atropine alone did not appear to affect the mice in any untoward way.

When dibutoline 2.5 mg per animal was injected alone it was found to cause 100 per cent mortality within ten minutes. As the dosage of dibutoline was decreased, the percentage mortality was decreased until with 0.313 mg per animal no deaths occurred. While dibutoline 1.25 mg per animal alone

TABLE I THE COMPARATIVE RATES OF PROTECTION PROVIDED FOR DFP BY DIBUTOLINE

	NUMBER OF MICE	DRUG (MG PER 25 GM ANIMAL)	NUMBER OF DEATHS	PERCENTAGE MORTALITY
Group A	39	DFP 0.125	15	38
	50	Atropine 0.02		
		DFP 0.125	6	12
	13	Dibutoline 2.50		
		DFP 0.125	13	100
	12	Dibutoline 2.50	12	100
	8	Dibutoline 1.25	7	87
	35	Dibutoline 0.625	18	51
	15	Dibutoline 0.313	0	0
	25	Dibutoline 1.25		
		DFP 0.125	10	40
	25	Atropine 0.02	0	0
Group B	24	Dibutoline 0.313		
		DFP 0.125	2	8
Group B	90	DFP 0.125	89	99
	25	Dibutoline 0.313		
		DFP 0.125	15	60
Group C	23	DFP 0.250	14	61
	28	Dibutoline 0.313	0	0
	44	Dibutoline 0.313		
		DFP 0.250	13	30

\*Cats were first tried and then discarded as experimental animals because of the great variation in response to a given dosage and the large amounts of drug needed for each animal.

caused a mortality of 87 per cent when it was followed by DFP 125 mg per animal, this mortality was reduced to 40 per cent showing that DFP has some protective action against the lethal dosages of dibutoline. DFP did not protect from the  $LD_{100}$  dosage of dibutoline (250 mg per animal). When the sublethal dose of 0.313 mg per animal of dibutoline was administered before the DFP the mortality was reduced to 8 per cent.

The second group of mice obtained from a different source, were more sensitive to DFP. The dosage 0.125 mg per animal DFP caused a mortality of 99 per cent in a large group of mice. This was reduced to 60 per cent by dibutoline 0.313 mg per animal.

The third group of mice was less sensitive to DFP so that 0.250 mg per animal caused a mortality of 61 per cent. This was reduced to 30 per cent by the dibutoline 0.313 mg per animal.

Death from either drug usually occurred within the first fifteen minutes and was rare after the first forty-eight hours. Thus dibutoline has a moderate degree of protective action against the toxic effects of DFP.

Analysis of these results to determine the probability that they might result from chance by the use of Pearl's formula for determining Chi square gave the following results. The probability of chance in group A is 1 to 110, group B, 1 to 500,000,000, and group C 1 to 80. These results, therefore, all fall within the definitely significant range.

#### SUMMARY

Dibutoline, a choline derivative with parasympathetic blocking and no stimulating action, was tested to determine if it would protect against diisopropyl fluorophosphate poisoning. Dibutoline was effective in protecting mice against DFP toxicity, as was atropine. Both drugs were moderately efficient as antidotes when their injection preceded that of DFP. DFP has some protective action against lethal doses of dibutoline.

## PHARMACOLOGY OF ALLYLTHIOMETHYL- AND n-BUTYLTHIOMETHYLPENICILLIN

C L ROSF, A B, P N HARRIS, M D, O K BEHRENS, PH D, AND  
K K CHEN, M D, PH D  
INDIANAPOLIS, IND

CONTRARY to the original conception, penicillin is now recognized as a group of substances having a chemical and biologic similarity. It is therefore a generic name. Benzylpenicillin (penicillin G) is the best known and most widely used of the group. New biosynthetic penicillins<sup>1</sup> recently have become available through the addition of certain organic precursors to the culture medium. Although different penicillins show a similar specificity of action on various microorganisms, several of the new penicillins exhibit pharmacologic properties which appear to offer some advantages over those of penicillin G. In this communication, certain physiologic actions of two of these penicillins,<sup>2</sup> allylthiomethylpenicillin (AT) and n-butylthiomethylpenicillin (BT), are compared with those of penicillin G.

Particular interest in the toxicity of these new penicillins by intradural injection was aroused by a report of Baker<sup>2</sup> of our laboratories. In screening some thirty penicillins for their action against rabie virus in the mouse brain, Baker found it necessary to establish their relative intracerebral toxicity values. His results indicated that penicillins AT and BT were much less toxic than penicillin G.

Direct application of penicillin G to the cerebral hemispheres frequently incites convulsions,<sup>3-5</sup> and in large doses may lead to necrosis of the parts so exposed.<sup>6-7</sup> The effectiveness of the barbiturates in alleviating convulsions is well known. Sodium Amytal (Sodium Iso-amyl Ethyl Barbiturate, Lilly) and phenobarbital sodium have been used successfully in the treatment of convulsive seizures due to penicillin G.<sup>8-9</sup> Thus, it was of interest to ascertain whether or not Sodium Amytal injected intravenously would also decrease the toxicity of penicillins AT and BT when injected intradurally.

The absorption, distribution, and excretion of injected penicillin, with particular reference to its presence in spinal fluid, have been investigated by several workers.<sup>10-14</sup> In our laboratories, studies were made on the concentrations of penicillins G, AT, and BT in the blood, urine, and spinal fluid of dogs following intradural and intramuscular administration. Since allergic responses to penicillin G have been reported in man,<sup>15-16</sup> and the sensitization of laboratory animals demonstrated,<sup>17-18</sup> similar experiments were undertaken with the penicillins under discussion.

From the Lilly Research Laboratories, Eli Lilly & Company

Received for publication Aug 24 1948

\*The natural and biosynthetic penicillins differ one from another according to the constituent present in the side chain containing the amide group. Benzylpenicillin (G) may be represented as  $C_6H_5-CH_2-R$ , allylthiomethylpenicillin as  $CH_2=CH-CH_2-S-CH_2-R$  and n-butylthiomethylpenicillin as  $CH_3-CH_2-CH_2-CH_2-S-CH_2-R$  where R represents the remainder of the penicillin molecule.

## PROCEDURES

Mice weighing 12 to 14 grams were selected for the intracerebral tests. The tops of their heads were painted with Tincture Merthiolate (Sodium Ethyl Mercuri Thiosalicylate Lilly), and injections made with a 0.5 inch 26 gauge short beveled needle, through the thin parietal bone near the sagittal suture. The compounds to be tested were dissolved in physiologic saline and injected in doses of 0.03 c.c. per mouse. Ten or more mice were used per dose, and the median lethal dose  $\pm$  standard error was computed by the method of Bliss.<sup>19</sup> Intracisternal injections were made on rabbits by means of a short beveled 20 gauge spinal needle. Clear fluid was withdrawn and various concentrations of the compounds in physiologic saline were administered in small volume doses (0.15 to 0.50 c.c.). Cisternal punctures on dogs were made through the space between the occipital bone and the posterior arch of the atlas. After the escape of a few drops of clear fluid, small volume doses in physiologic saline were injected. Intralumbal injections were also made in dogs in the third or fourth intervertebral space. Mice, rabbits, and dogs which died as the result of intradural injection were subjected to necropsy and sections of the brain and spinal cord examined microscopically.

In an attempt to decrease acute intoxication of penicillin in rabbits Sodium Amytal was injected intravenously in a dose of 30 mg. per kilogram immediately before lethal intracisternal injections of penicillin and again after the first convulsion.

Three dogs were injected, one each with a nonconvulsive dose (500 units per kilogram) of penicillins G, AT and BT respectively by way of the cisterna magna. Cerebrospinal fluid (CSF), blood and urine samples were collected hourly. The paper disc method of Loo and associates<sup>20</sup> for streptomycin adapted to the estimation of penicillin was used in the determination of the antibiotic content in the urine and cerebrospinal fluid. The blood concentrations were tested by a modification of the method described by Rammelkamp.<sup>21</sup> In an effort to find the rate of distribution of the penicillins from the blood into the cerebrospinal fluid, similar tests were made following intramuscular injection.

Sensitization experiments were conducted on guinea pigs. The animals were injected daily for five days by the intraperitoneal route with 500 to 1000 units of the respective penicillins. At the end of twenty one and forty two days they were tested for anaphylaxis by intravascular injection. In addition some of the animals were sacrificed and their isolated uteri tested for sensitivity to the compounds by the method of Schultz and Dale.<sup>22</sup>

## RESULTS

In contrast with the low toxicity following intravenous or intramuscular injection penicillin G when administered in relatively small doses into nervous tissue causes death. Compared with penicillins AT and BT, penicillin G is the most toxic. The data presented in Table I show that on a weight basis penicillin AT is  $\frac{1}{8}$ , and penicillin BT  $\frac{1}{18}$  as toxic as penicillin G when injected by the intracerebral route in mice. On a unit basis penicillin BT is  $\frac{1}{38}$  as toxic as the natural penicillin.

TABLE I TOXICITY FOLLOWING INTRACEREBRAL INJECTION IN MICE

PENICILLIN COMPOUNDS	UNITS PER MG	NUMBER OF MICE	LD <sub>50</sub> $\pm$ STANDARD ERROR	
			MG/KG	UNITS/KG
G	1.640	110	5.7 $\pm$ 0.23	9348 $\pm$ 377
AT	1.660	30	45.08 $\pm$ 3.91	7482 $\pm$ 6491
BT	3.330	30	100.74 $\pm$ 6.67	357000 $\pm$ 22211

*Streptococcus hemolyticus* O 93 was used in these assays. This organism responds somewhat differently from *Staphylococcus aureus* to the various penicillins. In order to express our findings in comparable terms the blood concentration values presented in Tables III and V have been corrected to correspond to units as determined with *Staphylococcus aureus* 4991.

Intracisternal injections of rabbits (Table II) show much the same relationships in toxicity. The differences, however, when tested by the same method on dogs are not as great. Penicillin AT is  $\frac{1}{6}$ , and penicillin BT  $\frac{1}{10}$ , as toxic as penicillin G.

TABLE II TOXICITY FOLLOWING INTRACISTERNAL INJECTION IN RABBITS AND DOGS

PENICILLIN COMPOUNDS	SPECIES	NUMBER OF ANIMALS	LD <sub>50</sub> $\pm$ STANDARD ERROR (MG/KG)
G	Rabbit	15	0.633 $\pm$ 0.065
AT		10	5.61 $\pm$ 0.65
BT		10	15.60 $\pm$ 2.00
G	Dog	10	1.118 $\pm$ 0.112
AT		10	6.49 $\pm$ 1.20
BT		11	11.50 $\pm$ 0.90

The most pronounced pathologic manifestation of the three penicillins following lethal intracerebral injections in mice and intracisternal injections in rabbits was necrosis of some of the ganglion cells of the cerebrum and Purkinje's cells of the cerebellum. The majority of the cells in both regions were normal. In dogs dying as a result of injections into the cisterna magna, much the same phenomena occurred. In sections from the cerebral cortex, basal ganglia, pons, cerebellum, and medulla, some ganglion cells were necrotic. Most necrosis was seen in the hippocampus major.

Sodium Amytal was found to be capable of preventing acute intoxication produced by intracisternal injections of penicillins G and AT in rabbits. The median lethal dose (LD<sub>50</sub>) for penicillin G was raised from 0.635 to 3.85 mg per kilogram when administered in conjunction with Sodium Amytal—a sixfold decrease in toxicity. Because of the small amount of penicillin AT available, its LD<sub>50</sub> with Sodium Amytal was not established. However, four rabbits when injected, respectively, with one to four times the LD<sub>50</sub> of penicillin AT, preceded and followed by the barbiturate, survived. Two rabbits receiving five times the LD<sub>50</sub> of penicillin AT, together with Sodium Amytal, died within thirty-six hours. No change in the LD<sub>50</sub> of penicillin BT occurred following the use of Sodium Amytal, phenobarbital sodium, urethane, or chloral hydrate.

Table III shows the data on the penicillin concentrations in blood, urine, and cerebrospinal fluid following intracisternal injections in dogs. A comparatively rapid clearance of the antibiotic substance from the spinal fluid occurred in each case.

When these compounds are injected by the intralumbar route in dogs, approximately five times as much material is required to cause death. Presumably, this may be due to the greater time required before the penicillin reaches the brain, giving an opportunity for dilution, as well as loss to the systemic circulation. This effect is demonstrated in Table IV.

The rapid transfer of penicillin from the spinal fluid following intracisternal injection in dogs suggested that adequate concentrations (0.03 unit per cubic centimeter or higher) might be obtained in the spinal fluid by intramuscular injection. Following a dose of 200,000 units an appreciable amount of the antibiotic substance was demonstrated in the spinal fluid, as shown in Table V.

Not included in the table are the almost negligible results produced by a dose of 20,000 units per kilogram

Eleven of sixteen guinea pigs sensitized to penicillin G showed a definite response on the twenty-first and forty-second days by the Schultz-Dale test. A group of nine showed no effect on the twenty-first day, but in another group of eight, five exhibited a mild anaphylactic reaction to intracardiac or intravenous injection of penicillin G. No response was obtained by either method when penicillin AT or BT was employed as the sensitizing and challenging agent. Nor was there any response to penicillins AT and BT in guinea pigs sensitized to penicillin G.

#### DISCUSSION

It has been demonstrated that penicillins AT and BT are less toxic by intradural injection than penicillin G. However, lethal doses of all three penicillins have the same pathologic effect upon the brain of mice, rabbits, and dogs, namely, production of necrosis of the ganglion cells.

The toxicity of penicillin G has been a limiting factor in its use in intradural therapy. The concomitant use of Sodium Amytal makes possible the administration of considerably larger doses. The median lethal dose of penicillin AT, which is much greater than that of penicillin G, can be increased further by the use of the same barbiturate. In sharp contrast, efforts to increase the  $LD_{50}$  of penicillin BT, the least toxic member of this group, have so far been unsuccessful. However, the toxicity of penicillin BT without Sodium Amytal is so low that the use of penicillin G or AT with Sodium Amytal offers no advantage.

The absorption, distribution, and excretion rates of these compounds in dogs are much the same, depending more on the size of the dose than upon differences in molecular structure. With the small number of dogs used, no significant differences could be ascertained. When relatively small doses are injected intracisternally, the penicillins studied are rapidly absorbed, distributed, and excreted. It is apparent that the barriers between the cerebrospinal fluid and the blood are relatively permeable to penicillins in the direction of spinal fluid to blood, although they hinder greatly the passage of the antibiotics in the direction of blood to spinal fluid.

Enormous intramuscular doses were required to give rise to definite quantities of penicillin in the cerebrospinal fluid. A dose of 20,000 units per kilogram was not sufficient, but ten times this amount resulted in high concentrations in the spinal fluid of all dogs. At no time, however, did the concentration in the cerebrospinal fluid approach that of the blood.

In view of the fact that penicillins AT and BT, in contrast with penicillin G, have shown no sensitization in guinea pigs, the new products may prove clinically more advantageous in allergic individuals. In all probability, penicillins AT and BT will not be contraindicated following penicillin G, because they have shown no cross-sensitization with this substance.

## SUMMARY

1 Allylthiomethylpenicillin (AT) and *n*-butylthiomethylpenicillin (BT) are much less toxic than penicillin G (benzylpenicillin) when applied directly to the central nervous systems of mice, rabbits, and dogs

2 The toxicity of penicillins AT and G in nervous tissue is reduced approximately fivefold by the intravenous administration of Sodium Amytal. The median lethal dose of penicillin BT, the least toxic of the group, is not affected by the use of the same barbiturate

3 Necrosis of the ganglion cells occurs following lethal, intradural doses of each of the three penicillins

4 The diffusion of penicillin appears to be much easier from the cerebrospinal fluid to the blood than in the opposite direction

5 Sensitization has been shown in guinea pigs to penicillin G, but not to penicillin AT or BT

The authors are indebted to Dr J M McGuire, Miss Louise Niles, and Miss Jean Smith for penicillin A, says Messrs G E Powell and J E Waddell for the Schultz Dale tests, and Messrs R D Fink and J K Henderson for their assistance in the toxicity and excretion experiments

## LABORATORY METHODS

### A METHOD FOR THE DETERMINATION OF FIBRIN APPEARANCE TIME

ARTHUR B. VOORHIES, JR., M.D., SAMUEL GREEN, PH.D., AND  
ARTHUR H. BLACKMOR, M.D.  
NEW YORK, N. Y.

ADEQUATE methods for control of administration of anticoagulants are of especial importance in light of the increased application of anticoagulant therapy in thrombophlebitis and in postoperative vascular surgical problems. Dicumarol therapy is regulated adequately by the determination of prothrombin time, a laboratory procedure; heparin administration, on the other hand, is usually controlled according to the blood coagulation time. The blood coagulation time determinations are routinely a bedside and not a laboratory procedure, and all too frequently the results are incorrect.

Among the sources of error in the Lee White<sup>1</sup> and the de Takats methods or their modifications are the agitation incurred in venipuncture and transfer of specimens, the variation in agitation of the specimens and especially the non-uniform sensing of the end point by different observers. The scrupulous cleanliness and uniformity of glassware necessary and the difficulty of temperature control also combine to make the methods cumbersome and of doubtful application to the control of heparin therapy. On the whole these methods require an attention to detail difficult to accomplish on the wards.

In this report we introduce a new criterion for the control of heparin therapy which is not in the true sense a blood clotting method but rather a measurement of the fibrin appearance time. The technical procedure follows.

A capillary tube varying from 1 to 2 mm in diameter and of approximately 5 cm in length is the basic piece of equipment. The tubes are cleaned by dichromate solution followed by thorough rinsing in distilled water. Prior to the test, a 100 cc. Veronal saline buffer solution† (pH 7.4) containing 400 mg. fibrinogen‡ is made up. This solution has been found to remain relatively stable at room temperature for at least twenty-four hours. A small quantity of the fibrinogen solution is drawn up into the capillary tube and any excess solution remaining at the tip of the tube is removed by touching the tip to any clean absorbent material. The finger tip is cleansed thoroughly with alcohol, allowed to dry, and jabbed with a sharp instrument so that a drop of blood will appear immediately without the necessity of milking the finger. The tip of the capillary tube is touched to the drop of freshly drawn blood and a quantity roughly equal to that of the fibrinogen solution already present is allowed to rise into the tube.

by capillarity. The end is sealed carefully with petroleum jelly, and the capillary tube is placed in a constant temperature bath at  $37.5^{\circ}\text{C}$ . A bright light placed behind the capillary tube enhances the visibility of the fibrin formation. The end point is read when the first cloudy haze appears at the blood-fibrinogen solution interface, and is not to be confused with the plasma layer formed when the blood cells sediment. The time of the test extends from the moment blood is drawn from the finger to the moment the cloud at the interface appears.

Fig 1—Diagram of the Lucite water bath used to maintain a constant temperature of the capillary tubes

The theoretic basis of the test is the accepted concept that fibrinogen in solution is converted to fibrin by the action of thrombin formed in the blood. Since thromboplastin in the presence of calcium ion effects the conversion of prothrombin to thrombin, which in turn converts fibrinogen to fibrin, it would appear that if a clear solution of fibrinogen were to be brought into contact with whole unclotted blood, thrombin activation by blood and tissue thromboplastin would be reflected immediately by fibrin conversion in the portion of the fibrinogen solution contiguous to the whole blood. The arrangement which appeared to offer the greatest degree of simplicity was that of layering blood drawn into a capillary tube with a fibrinogen solution. Through observation of such

an arrangement it can be seen that a definite area of fibrin forms in the clear fibrinogen solution just above the blood fibrinogen interface. Using a capillary tube provides an additional advantage in that the rate of diffusion of what is presumed to be thrombin is held relatively constant. It is reasonable to suppose that the conversion of fibrinogen to fibrin at the interface goes on simultaneously with the conversion of fibrinogen to fibrin in the fresh whole blood below. The immediately apparent advantages are that the fibrin formation goes on in a solution which is perfectly clear and not obscured by the whole blood, that agitation is minimal, and that observation can be carried out with ease in a constant temperature bath.

Fig 2—Photograph of the end point in the capillary fibrinogen method. The source of light is behind the capillary tube.

The simplicity of sampling finger tip blood employed by the de Takats method is favored, although it is well known that blood obtained from finger tip sampling exhibits greater thromboplastic activity than that derived from venipuncture, however. In the data that are to be presented it appears that the summation of tissue and blood thromboplastic activity bears a direct relation to the quantity of heparin given.

A 400 mg per cent solution of fibrinogen was chosen because it approximates the upper limits of normal blood fibrinogen concentration. Various solu-

tions containing from 100 to 800 mg per cent fibrinogen were tried without any appreciable difference in fibrin appearance time or in the visual density of the fibrin formation. Veronal buffer was used with a pH of 7.4 since the fibrin formed was slightly more opaque than that seen with fibrinogen in physiologic saline. Capillary tubes with bores varying from 0.5 to 2.0 mm were used without introduction of any appreciable error.

\*The control values here are higher than those found in routine clotting determinations on normal individuals for two reasons. Determinations were made in test tubes with a diameter of 12 mm rather than the routine 8 mm and were conducted at a temperature of 25° C rather than 37.5° C. The normal time spread at 37.5° C in 8 mm diameter tubes is eight to fifteen minutes.

A large series of presumably normal individuals were tested and it was found that the spread of normal fibrin appearance time fell within five to seven minutes. When repeated tests were run with a single individual the variation was approximately thirty seconds.

A series of patients receiving heparin was tested simultaneously with the fibrin appearance time determination and the Lee White coagulation time

Fig 3 —Heparin tolerance test

Fig 4 —Heparin tolerance test.

method There was a rough correlation between the two times but a constant relationship was not apparent (Table I)

In an additional attempt to establish a strict correlation, 20 mg of heparin (Liquaemin) were given intravenously to a subject, and at predetermined intervals triplicate tests were run both by the Lee-White coagulation time method and the fibrin appearance time method Again the times were roughly parallel, but there was no precise constant (Table II)

Our attention was focused on the alteration of fibrin appearance time by heparin administration Fig 3 presents the findings obtained when 10 mg of heparin (Liquaemin) were given intravenously to a normal individual Three hours following the initial dose of 10 mg, 20 mg were given intravenously The

Fig 5 —Effect of temperature on clotting time

prolongation of the fibrin appearance time was immediate in both instances, and subsequent drops in the fibrin appearance time progressed in a linear and parallel fashion as the effect of the drug diminished Fig 4 depicts a similar test in another normal subject, substantiating the fact that among presumably normal individuals there is considerable difference of response to heparin In the second subject the initial prolongation of the fibrin appearance time was much greater and the subsequent fall-off was more rapid

It was found that if heparin is given after a lapse of several days, the individual's response may be markedly altered (Fig 4) Seventy-two hours following the initial intravenous heparin dosage, 20 mg of Liquaemin were given intravenously The individual's response had been markedly altered Height and duration of the curve had diminished

In order to determine the importance of temperature control repeated fibrin appearance time determinations were made on the same individual and were carried out in a water bath in which temperature was carried from 20 to 40° C (Fig 5). At the lower temperatures the expected prolongation of the fibrin appearance time occurred.<sup>3</sup> At 30° C the time reached its shortest interval but as body temperature was approached it again rose. Just above normal body temperature it again fell but to low levels leveling off at 40 to 45° C. What significance this observation may have is unknown but it does give rise to speculation as to whether the same phenomenon occurs in vivo as in vitro.

#### SUMMARY

A method for the determination of fibrin formation time based on the diffusion of thrombin into a fibrinogen solution is described. The method appears to reflect more accurately heparin activity in vivo than the conventional clotting time determinations. The method lends itself to heparin studies on small animals more readily than the Lee White method. Data presented suggest the possibility of the development of an increased tolerance for heparin on periodically repeated intravenous dosage. It appears that fibrin appearance time varies sharply with in vitro temperatures that are within physiologic limits.

## A DESCRIPTION OF THE APPARATUS

An old foot operated sewing assembly was removed from its base and fitted to a small wooden platform so that it could be placed on a laboratory bench. A circular wooden disk, 10.2 inches in diameter and 0.7 inches thick was then bolted to the drive wheel. The disk contained eight equally spaced small, utility clamps from which the clamp holders had been removed. The clamps were located one inch from the periphery of the disk and fastened in place with the customary locking brass wing nut accompanying clamps of this type. The disk was in turn rotated by a small motor of the type commonly used for converting sewing machines (Fig. 2).

# AN ELECTRONIC APPARATUS FOR RECORDING BLOOD PRESSURE

DAVID F. MARSH, PH.D.  
MORRISTOWN, N. J.

MANY biologic assays and pharmacologic investigations depend on the measurement of the mean arterial blood pressure. This is commonly accomplished by the use of the Ludwig mercury manometer writing on soot covered paper. The soot covered paper is messy, difficult to label and susceptible to cracking or sticking during storage depending on the type of fixative used. Although the disadvantages of the soot and stylus procedure can be partly overcome by the use of a writing point using ink, this device requires constant attention to keep the ink reservoir filled and the recording paper must be run fairly rapidly to avoid having the ink smear and run.

With sufficient patience and experience satisfactory records can be obtained with either of these techniques but the mercury manometer suffers the additional faults that a fairly large hole must be made in a major artery that some blood loss is always involved and that an anticoagulant must be used. These factors make the use of unanesthetized animals or small animals difficult. Some of these defects can be overcome by the use of the rubber diaphragm manometer but the device is nonlinear in response and possesses the same recording defects.

The Hamilton<sup>1</sup> and Wiggers' optical recording manometers are precision instruments that give a true record of systolic and diastolic blood pressure from which the mean arterial pressure can be calculated. Hypodermic needles are used for cannulas and blood pressure can be measured without the necessity of making large incisions. These devices are difficult to set up and to maintain in operation, must be used in partial darkness, and since they record on photographic paper there is a considerable time lag between the administration of a drug and observation of the results. Recently Braunstein and co workers<sup>2</sup> have suggested the use of strain gage manometers recording through a string type electrocardiograph, but this also suffers the difficulties inherent in any method of photographic recording.

All of these difficulties can be overcome by the use of the following apparatus, the components of which are commercially available. A Lambert Wood<sup>3</sup> strain gage manometer\* has its two input terminals connected to a 75 volt A battery,<sup>†</sup> and its output terminals connected to a General Electric photoelectric type recording microammeter ‡. By reducing the size of the plastic head on the manometer and using a hypodermic needle adapter instead of a tubing connection, it is possible to mount the manometer directly on the animal. This has obvious advantages when it is desired to expose the animal to artificial changes

Fig 1—Left to right recording microammeter battery for strain-gage pressure bottle containing heparinized saline for washing out manometer and modified Lambert-Wood strain-gage manometer. The hypodermic needle cannula is coated with General Electric Dri-film 9987 & silicone resin to lower the incidence of clotting at the tip

Fig 2—Typical record Dog (11 kilograms male 320 mg sodium barbitol per kilogram intraperitoneally) Strain gage manometer in left carotid artery mercury manometer connected to right carotid artery Five micrograms of epinephrine (base) per kilogram given at E 5, and 1 mg Propadrine hydrochloride per kilogram given at PROPADRINE Time vertical lines minutes pressure horizontal lines 4 mm Hg units Sections of the mercury manometer record run only one-fifth as fast, have been superimposed for purposes of comparison

of environment as only the electrical connection to the recorder need be run outside of the experimental chamber. Since very little volume exchange occurs with this type of manometer, no blood loss nor introduction of large amounts of anticoagulant solution need occur and unanesthetized animals can be used and pressure measured as long or as frequently as necessary. The device has been used to measure the blood pressure of rats, rabbits, guinea pigs, cats, and dogs. With suitable precautions as to sterility of the cannula and solution it could be used in man.

The recording microammeter is simple to operate, ruggedly constructed and portable. The ink written record is always visible and annotations can be made on it in ink or pencil at any time. It is not subject to destruction by folding, warmth, or scratching as are some of the electrolytic and plastic recording papers, and it can be easily mounted with glue or rubber cement. The rolls are available with various rulings or plain. Various gear trains are available so that almost any desired rate of movement of the recording paper can be obtained. By choosing from the many basic instrument movements available and matching with the strain gage sensitivity almost any desired deflection sensitivity can be obtained. If necessary, the sensitivity can be increased by using a higher voltage battery or decreased by the use of a low ohmage variable resistance between the manometer and recorder. The electronic circuit is slow enough that damping of the systolic diastolic pressure to an integrated tracing of the mean arterial blood pressure occurs, and the minor fluctuations seen with the mercury manometer are absent.

#### SUMMARY

The disadvantages inherent in the common methods of the measurement of mean arterial blood pressure can be overcome by the use of a Lambert Wood strain gage manometer and a portable recording microammeter.

# AN OPTICALLY RECORDING BUBBLE FLOW METER ADAPTED FOR MEASUREMENT OF RENAL BLOOD FLOW

EWALD E SELKURT, PH D  
CLEVELAND, OHIO

THE principle of measurement of the mean rate of blood flow by timing the passage of a small air bubble introduced into the blood stream of an organ was first used by Soskin, Priest, and Schutz<sup>1</sup>. Blood leaving the femoral vein of a dog passed through an external circuit of glass tubing of small bore. Knowing the exact volume from the point of entrance to the point of exit of the tubing and the time of passage of the bubble between these two points permitted calculation of volumetric flow. Dumke and Schmidt<sup>2</sup> have more recently employed a modification of this principle for estimation of cerebral blood flow by measuring arterial inflow, and the same apparatus has been used for coronary arterial inflow measurement<sup>3</sup>. Both devices have required direct visual observation for timing bubble passage. However, when measurement of renal blood flow is to be made in dogs, rates up to 200 cc per minute are not uncommon and time of bubble passage is correspondingly brief. To insure complete accuracy a photoelectric cell was incorporated into the present modification to measure the time of bubble passage. This has the additional advantage that it can be used to actuate an optically recording galvanometer so that flow can be registered simultaneously with blood pressure measurements on the photokymograph.

*Description of Apparatus*—(Numbers in parentheses refer to corresponding parts of the apparatus pictured in Fig 1). The main circuit consists of Lucite (Plexiglas) coiled tubing of about 3 mm internal diameter and 60 cm length. Blood enters and leaves the tubing through a Lucite block through which the bore of the tubing is continuous (10). A metal plate containing two slots directly overlying the continued bore of the tubing covers the Lucite block. Through these slots light from a 6 volt auto lamp (9) is transmitted to an underlying photoelectric cell (11). Air from a reservoir under pressure somewhat higher than carotid blood pressure is introduced at (6) via a three-way stopcock (5) into a 2 cc syringe (2), and from this volumes of about 0.3 cc are injected into the inflow limb of the meter. Passage of this bubble under the "entering" and "exit" slots suddenly transmits light through the column of blood to the photocell. This impulse is amplified by a G. E. Victor electrocardiograph, causing the mirror of an auxiliary galvanometer of the torsion-string type to register a deflection of a light beam (see record, lower part of

From the Department of Physiology, Western Reserve University School of Medicine.  
This investigation received financial support from the Council on Pharmacy and Chemistry, American Medical Association.  
Received for publication Sept. 2, 1948.

Fig 1—Top optically recording bubble flow meter utilizing photoelectric cell to record time of bubble passage. The numerals refer to various parts which are described in the text. Bottom optical record showing (from above downward) manometer base line renal arterial pressure and galvanometer record showing characteristic deflections as bubble passes entering and exit slots of meter. Volume of the flow meter circuit between slots is 6 cc hence observed flow is  $6 / 44 \times 60 = 147$  cc. per min. corrected flow (from Fig 2) is 130 cc. per minute.

Fig 1) The air bubble is then captured in a trap made from large diameter glass tubing with a side arm (3). As an accumulates it is released through a stopcock (1).

Measurement of the rate of arterial inflow is provided for by cannulation of a carotid artery and connecting with lead tubing to the inflow coupling of the meter (4). The blood leaves the meter at (8) which connects directly to a metal "L" cannula (not shown in the figure) suitable for cannulation of the renal artery. At this point another coupling (7) permits connection to an optical manometer of the Gregg type for registration of renal arterial pressure.

No provision has been made for constant temperature regulation of the flow meter. At normal rates of renal blood flow, temperature drop across the meter is hardly perceptible. Indeed, for a flow of 42 cc per minute, a temperature drop of only  $0.25^{\circ}\text{C}$  was noted with ambient temperature of  $23^{\circ}\text{C}$ . Any cooling of the animal can be prevented by use of a warming board.

*Calibration of the Instrument*—To calculate volumetric flow, the exact volume of the flow meter from mid-point to mid-point of the "entering" and "exit" slots must be known. Time of passage is obtained from the electrical

Fig. 2—Calibration graph showing the relationship of observed flow to direct volumetric flow. The dotted line indicates perfect correlation.

timing device of the photokymograph. It was found that the air bubble traveled somewhat faster than the total column of blood, making the observed flow faster than the simultaneously measured volumetric outflow. This is a linear relationship directly proportional to the rate of flow and the total length of the flow-circuit. Hence a calibration curve of the type illustrated in Fig. 2 must be constructed by making simultaneous direct flow determinations with bubble flow at different rates. Hematocrit concentration does not appear to significantly influence this relationship as shown in Fig. 2.

*The Effect of the Bubble Meter on Renal Arterial Pressure and Pulse*—The blood meets resistance to flow in the meter circuit, causing mean renal arterial perfusion pressure to be less than mean systemic arterial pressure. The

pressure drop in the meter used here is 16 mm Hg when blood flows through the meter at a rate of 100 cc per minute (average hematocrit reading 38 per cent). Pulse pressure averaged 18 mm Hg for a number of observations at an average heart rate of 110 per minute. Due to the damping effect of the meter there is a change in normal arterial pulse contour resulting in a more gradual rise of the pulse and a considerable damping of the measure (Fig 1). As air accumulates in the bubble trap the change in contour becomes more marked, finally giving a triangular contour with no measure accompanied by further reduction in pulse pressure.

Fig 3—Representative experiments in two animals showing reflex vasomotor effects on kidney blood flow. A sciatic stimulation (traction) B central vagal stimulation (Electrodynic stimulator 1.0 volts, 50 per second)

**Preparation of Animal**—Dogs anesthetized with 30 mg per kilogram of body weight of pentobarbital sodium administered intravenously, are used. Utilization of the arterial inflow principle necessitates exposure of the left renal artery by a dorsal retroperitoneal approach. About 1 cm of the renal artery close to the abdominal aorta is dissected free of nerve fibers, if this is done carefully they need not be interrupted. Before cannulation of the artery, the animal is heparinized with 4 mg per kilogram of body weight priming dose, and a total of 5 mg of heparin is given every half hour thereafter. Cannulation requires first ligation of the artery close to the aorta before incising. The renal cannula is then introduced toward the kidney and secured with a second ligature. Total time of this procedure should be less than one minute.

**Representative Results**—From various observations made on a number of animals, only two illustrative experiments demonstrating reflex effects on flow are presented herewith (Fig 3). A shows decreased flow accompanying a pressor response following central sciatic nerve stimulation in one animal, and B shows a phase of reduced flow accompanying a pressor response during

strong central vagal stimulation Since flow is reduced while arterial pressure is elevated, active reflex vasoconstriction must be occurring in the kidney This proves the intactness of the renal nerve supply

#### CONCLUSIONS

Advantages of the optically recording bubble flow meter are (a) it records mean flow, and readings can be very rapidly repeated, e g, every five seconds, (b) moderate amounts of heparin can be used, for clotting is minimal on the nonwetable surface of the Lucite tubing Furthermore, small amounts of fibrin formation should not change the calibration of the instrument appreciably This is not the case with other currently used optical flow meters such as the rotameter With this, anticoagulant dyes such as pontamine fast pink and chlorazol fast pink are required as an adjunct to heparin These dyes are not without their effect on renal blood flow (unpublished observations)

The disadvantage of the present device is that there is appreciable loss of perfusion pressure through the meter and some damping of the pulse pressure Observations here indicate that while reduction in pulse pressure does not influence renal blood flow, decrease in mean perfusion pressure will obviously reduce flow to some degree Accordingly, the best use of the instrument is for measurement of changes from control value resulting from neurogenic or humoral and drug action, particularly when experimental changes are rapid

### HEMOPHILIA LIKE DISEASE IN WOMEN

#### REPORT OF TWO CASES

JAMES S. HILWETT, M.D. AND RUSSELL L. HADEN, M.D.

CLEVELAND, OHIO

**W**HETHER or not hemophilia can occur in women has never been conclusively determined. Hemophilia is a disease characterized by delayed clotting of the blood, is transmitted through women and occurs exclusively in men. However, a few cases which clinically resemble hemophilia in women have been reported. We have recently encountered two such patients.

**CASE 1**—A woman, aged 40, was first seen on Jan. 31, 1945, with the complaint of sudden hemorrhage into the base of her tongue that interfered with eating and caused pain and difficulty upon swallowing. She had first noted large hemorrhages into the subcutaneous tissue of her right arm with some swelling and pain in August, 1944. These multiple areas of ecchymoses had appeared several days subsequent to a bee sting on her right hand which resulted in severe local redness and swelling. The subcutaneous hemorrhages had continued and one week later had spread to involve the left arm in a similar fashion. She had noted hematuria on one or two occasions and some bleeding from the mouth. The episodes of hemorrhage continued with variable frequency involving various portions of the body.

The patient's father had died at the age of 77 of arteriosclerosis and her mother was living and well at the age of 85. Two brothers, aged 62 and 64, were alive and well and no siblings were deceased. There was no family history of abnormal bleeding or bruising for at least two generations. The past medical history was negative except for scarlet fever at the age of 24 which left no sequelae. The patient had had one miscarriage followed by five normal births, the last being in May, 1944, without abnormal bleeding. Her menstrual periods had always been regular every twenty-eight days, lasting five days without excessive flow.

Physical examination was entirely negative except for many large subcutaneous hemorrhages over the entire body. The laboratory findings are summarized in Table II. Sternal puncture disclosed an erythroblastic marrow but was otherwise negative.

From January, 1945, until April, 1945, the patient was given six intravenous injections of plasma by her own physician. She thought she was much improved during this period. In April she sustained a large bruise on the forearm following trauma, but the spontaneous hemorrhage in general was much less frequent. Hemorrhagic studies made in January, 1946, are summarized in Table II. In March she delivered a normal child and showed no tendency to abnormal bleeding. In June, following extraction of a tooth, continuous oozing was present for two days and her entire jaw became "black" for a few days then returned to normal. She was observed again in August with no evidence of bleeding or bruises.

From the Division of Internal Medicine, the Cleveland Clinic and the Frank E. Bunts Educational Institute.

Received for publication July 6, 1948.

CASE 2—A woman, aged 33, was admitted on Feb 14, 1944. In January she had noted some swelling and tenderness of one of the finger joints, which was interpreted as a mild arthritis at the time. She denied any traumatic factors. Later there had been evidence of bleeding in the area of the joint, followed by a similar swelling and tenderness of the right wrist with hemorrhage extending up the right arm. There was subsequent involvement of the left ankle and left leg, with large hemorrhagic areas over the entire left leg and foot. During this period the patient had epistaxis on several occasions from the right nostril only, usually occurring in the early morning or associated with reclining, and persisting from five to forty minutes. The flow was by drop rather than by steady stream and had never been difficult to control. Hematuria had been noted for one week in January, but this had cleared spontaneously and had not recurred. Associated with the appearance of ecchymoses and bleeding into the joints, the patient had noticed pronounced malaise and physical weakness and had become unable to carry on her household duties.

Family history was negative, and careful questioning did not reveal evidence of any familial hemorrhagic tendency on either the maternal or paternal side. There were nine maternal and eight paternal siblings and two sisters of the patient, both of whom were born deaf but were otherwise normal. The past medical history was entirely normal. On Jan 19, 1943, she had delivered a normal baby boy after full term pregnancy with no unusual loss of blood. There had never been any abnormality in the menses.

Physical examination was entirely negative except for ecchymotic areas about the right elbow, inside the right and left thighs, and on the left ankle. There were no manifestations of joint involvement. No petechiae were present.

In March, 1944 the patient was given 250 ml of lyophilized plasma by intravenous infusion. The coagulation time was reduced from two hours and fifteen minutes to one

hour and thirty minutes. This procedure was repeated a few days later and no reduction in the coagulation time was observed. When he was last seen at the Clinic in September 1944, the coagulation time was only one hour and forty five minutes. A telephone conversation in August, 1946 revealed that he was continuing to have ecchymoses and minor joint symptoms. The laboratory data are summarized in Table III.

TABLE III

	FEBRUARY 1944	MARCH, 1944	AUGUST, 1944	SEPTEMBER 1944
Tourniquet test	NEG.

## DISCUSSION

In the past sixteen years at the Cleveland Clinic this type of hemorrhagic diathesis occurring in female patients has been observed on only two occasions. It is undoubtedly a rare condition. Nevertheless we believe that this hemorrhagic problem occurs more frequently than is realized but remains undiagnosed. It is interesting to speculate as to whether or not such women bleeders have the same inherent defect in the blood as that present in true hereditary hemophilia.

Bullock and Hildes,<sup>1</sup> in a survey of 600 hemophilic families, could find no evidence of the disease among the female subjects. Birch<sup>2</sup> in the United States reviewed seventy-eight hemophilic families and could find no affected women among them. Others<sup>3</sup> have made similar investigations and have found no true female hemophiliacs. Bueuri<sup>4</sup> collected 197 cases of "female hemophiliacs" from the literature but he found the evidence equivocal and inconclusive for such a diagnosis in all of the cases. As Quick<sup>5</sup> points out "all of the cases of so called hemophilia in women, antedating the very recently reported ones, must be restudied in the light of newer diagnostic procedures and the diagnosis cannot rest on history and a prolonged coagulation time of the blood alone. According to Quick, 'It is extremely doubtful whether a true case of hemophilia has ever occurred in a woman.'"

In 1945 Madison and Quick<sup>6</sup> described this disease entity as "hemophilia like disease in the female" and gave an account of a woman aged 30 who developed hemorrhage into the deep tissues of the body and evidence of hematuria. She had a prolonged coagulation time, but the coagulation time

of recalcified plasma was normal. She developed severe hemorrhage into the tongue and the pharynx which led to mechanical obstruction of respiration and subsequent death. Autopsy revealed nothing other than extensive hemorrhage throughout the body. These authors also reported the case of a woman, aged 33, in whom hemorrhagic manifestations appeared one year following childbirth. The hemorrhages were for the most part superficial, with epistaxis and one attack of hematuria. The prothrombin time was 88 per cent, and the coagulation time was one hour and fifty minutes. The family history was negative. Joules and MacFarlane<sup>7</sup> in 1938 described the similar type of bleeding in a 56-year-old woman. Following extraction of a tooth she developed hemorrhages into the subcutaneous tissue, hematuria, and bleeding into the tongue and joints. She had a prolonged coagulation time. When Russell's viper venom was added to the blood in the tube the coagulation time became almost normal. Other cases of female bleeders, such as those reported by Kubo,<sup>8</sup> Schultz,<sup>9</sup> and Chargaff and West<sup>10</sup> resemble hemophilia more closely than they do any other hemorrhagic disease. It is obvious that these along with the two we have reported, belong to an entity that has a coagulation defect in the blood not unlike that of true hemophilia.

Whether or not an inhibitor substance is present in the blood of hemophilic persons accounting for the hypocoagulability has not been conclusively determined. Recently Tocantins<sup>11</sup> has presented evidence suggesting that the primary disturbance in hemophilia is associated with an excess of antithromboplastin. Others<sup>12</sup> hold that the theory of an anticoagulant as the cause of hemophilia is untenable. The presence of such an anticoagulant has been suggested as an explanation for the hypocoagulability of other hemorrhagic diseases. Such an anticoagulant had never been observed in human blood, however, until Lozner, Jolliffe, and Taylor<sup>13</sup> reported a patient with a prolonged coagulation time which they proved to be associated with an anticoagulant in the blood. Therefore, these authors suggested that such bleeding problems be investigated and a search made for the presence of an anticoagulant in the plasma. Fantl and Nance<sup>14</sup> also have reported a woman who acquired a hemorrhagic diathesis which they proved to be due to a specific antithromboplastic factor.

Following the technique described by Lozner, Jolliffe and Taylor,<sup>13</sup> we have attempted to exclude the possibility of an anticoagulant in our second patient. For this experiment blood was obtained from a normal donor and from our patient. The plasma was prepared from both blood specimens by adding sodium citrate to the whole blood so that the final citrate concentration was 0.25 per cent. The blood was then centrifuged, the plasma was removed and filtered through a Seitz filter. The normal blood had a clotting time of nine minutes. When 0.1 ml of filtered citrated plasma from our patient was added to 2 ml of normal whole blood, it continued to clot at the same rate of nine minutes. This seems to eliminate the possibility of the presence of an anticoagulant in the blood plasma as the basis for the retarded coagulation time.

The next experiment was made with blood obtained from the same patient a normal donor and a hemophilic patient. The same technique was followed in preparing the plasma. When 0.1 ml of normal citrated plasma was added to 2 ml of hemophilic blood there was an acceleration of the coagulation time from fifty seven minutes to twelve minutes. Under the same conditions 0.1 ml of normal citrated plasma was added to 2 ml of the patient's blood. There was a similar acceleration of the clotting mechanism and the coagulation time was reduced from 130 minutes to thirty minutes. We next added 0.1 ml of plasma from the hemophilic subject to 2 ml of blood obtained from the patient. The time required for the coagulation to occur was not altered remaining at fifty seven minutes. (These figures are summarized in Table I.) These facts seem to indicate that normal plasma contains a substance which is absent or deficient in the blood of the hemophilic person and of our patient. Whether the deficient factor is the same in both instances is not known.

Some of the more recent work by Patel and Taylor<sup>11,12</sup> and then as associates<sup>13,14</sup> has shown that normal cell free human plasma contains an active principle which when added in small amounts to hemophilic blood produces normal coagulation. This substance is closely allied with the globulin fraction of the plasma proteins and has been designated the 'globulin substance'. They were unable to obtain it in any significant quantity from hemophilic plasma. Howell<sup>15</sup> has confirmed these observations but prefers to call the material plasma thromboplastin. There seems to be fairly conclusive evidence that there is a deficiency in the plasma of hemophilic patients which accounts for the prolongation of the clotting time. More recent investigation suggests that this globulin fraction acts as the progenitor of an enzyme system which plays an as yet unknown role in the process of blood coagulation. In hemophilic plasma the enzyme system may be present in reduced amounts. Along this line Quick<sup>16</sup> has recently presented evidence that the platelets are normal in hemophilia liberating their enzyme in a normal manner. He proposes that this platelet enzyme acts directly on the precursor of thromboplastin which he designates thromboplastinogen. Hemophilic patients thus lack this precursor thromboplastinogen which is normally present in the plasma.

We were therefore interested in seeing whether any disturbance in the plasma protein fractions could be demonstrated. Employing the technique of Tiselius\* we determined the various plasma proteins. These are recorded in Table IV. In our first patient there was a low value for the total protein and for the albumin which could be accounted for by blood loss. The globulin fractions and fibrinogen were within the range of normal although the alpha globulin was at the lowest value of normal. In our second patient the total protein was normal the albumin was normal but the alpha globulin was abnormally low. The beta and gamma globulin and the fibrinogen fractions

\* Longworth's<sup>17</sup> modification of the Tiselius electrophoretic method was used to estimate the albumin,  $\alpha$  globulin,  $\beta$  globulin and  $\gamma$  globulin and fibrinogen in the plasma. Total protein values were determined by Pregl's modification of the micro Kjeldahl method for estimating total and nonprotein nitrogen.

TABLE IV TISELIUS PROTEIN FRACTIONATIONS (GM/ML)

NORMAL RANGE	TOTAL	ALBUMIN	$\alpha$ GLOBULIN	$\beta$ GLOBULIN	$\gamma$ GLOBULIN	FIBRINOGEN
High	7.82	5.11	0.66	1.07	0.91	0.48
Low	5.94	3.72	0.39	0.65	0.60	0.16
Case 1	5.30	2.78	0.39*	0.80	0.91	0.42
Case 2	6.40	4.21	0.31*	0.88	0.72	0.28

\*Definitely low values

were normal. Both of these protein patterns can we believe, be considered abnormal. The alpha-globulin fraction has been reported low in hypothyroidism, and hypopituitarism, which neither of our patients had. The significance of this discrepancy in the alpha-globulin is not known.

## SUMMARY

1 The clinical picture in two cases of hemophilia-like disease in women was similar to that found in true hemophilia and the outstanding characteristic was the prolonged coagulation time of the blood.

2 The coagulation time of recalcified plasma, which Quick<sup>27</sup> believes pathognomonic for hemophilia, was positive in both patients.

3 When normal citrated plasma was added to blood from one of our patients the coagulation was markedly accelerated. This is similar to the response of hemophilic blood to normal plasma.

4 Tiselius protein fractionation revealed definite abnormality in the alpha-globulins in one patient and suggestive but not conclusive evidence of abnormality in the second patient. We believe that these changes are significant.

5 The possibility that some acquired change in the plasma protein pattern might be the basis for the coagulation defect in our patients is suggested. The defect seems similar to that found in hemophilia.

## THE LYMPHOCYTE

STUDIES ON ITS RELATIONSHIP TO IMMUNOLOGIC PROCESSES IN THE CAT

CHARLES G CRADDOCK, JR, M D, WILLIAM N VALENTINE, M D, AND  
JOHN S LAWRENCE, M D  
ROCHFSTER, N Y

THE part played by the lymphocyte and lymphoid tissue in the normal physiology of the body and in the response of the latter to injurious stimuli and disease states has been the subject of many speculative theories, but a surprising paucity of well-established information exists in regard to the functions of this widespread tissue. It is quite apparent that the lymphocyte must be of considerable significance in the general body economy if one but considers the rate of utilization and concomitant production of lymphocytes in the normal animal. It is reasonably well established that each lymphocyte must yield its metabolically important contents within a few hours after entering the blood stream<sup>1, 2, 3</sup>. Recent investigations have directly implicated the lymphocyte and lymphoid tissue in important immunologic functions—a relationship which previously had been postulated many times but never adequately substantiated experimentally. Because of the great significance of such a concept in regard to clearer understanding of the body's defense processes, thorough evaluation of the existing knowledge is essential.

Many and diverse sites of antibody formation have been implicated by different investigators. Reticulo-endothelial tissue has attracted particular attention in this regard. Thus Hartley<sup>4</sup> reported evidence of antibody formation occurring in the histiocytic cellular reaction about the intradermal injection of an aluminum hydroxide gel suspension of vaccinia virus. Experiments by Topley<sup>5</sup> in 1930 seemed to indicate that the "histiocytes of the spleen themselves form antibodies or some intermediate product." Similarly De Gaia and Angevine<sup>6</sup> found antibody in tissues rich in reticulo endothelial cells before any antibody appeared in the blood. The inhibition of antibody response by any procedure which severely injures the cells of the reticulo-endothelial system<sup>5, 10</sup> is further indirect evidence of the role of the latter in the formation of antibodies. Tissue culture experiments likewise support the contention that reticulum cells such as those found in bone marrow lymph nodes, and spleen are capable of producing antibodies. In fact, Meyer and Loewenthal,<sup>11</sup> employing the rabbit, reported antibody formation from cultures of omental milk spots, a tissue which contains only cells of the reticulo-endothelial type. The plasma cell has also been felt to take part in immunologic processes<sup>12, 13</sup>. However, there is disagreement as to the primary importance of the plasma cell in antibody formation<sup>14</sup>.

This work was performed under contract number W-7401-eng-49 with the Atomic Energy Commission, University of Rochester.

From the University of Rochester School of Medicine and Dentistry and the Department of Medicine of the Strong Memorial and Rochester Municipal Hospitals.

Received for publication Aug 13 1948

In spite of the diversity of opinion as to the relative importance of various tissues in the antibody mechanism, recent findings revive the concept that lymphoid tissue and its product, the lymphocyte, are fundamental in the process. In 1935 McMaster and Hudaek<sup>16</sup> first reported evidence of agglutinin formation in the local lymph nodes draining the area of intradermal injection of antigen into mice before detectable antibody appeared in the blood. Similar results later were obtained in rabbits. Since then numerous workers<sup>17-20</sup> have concluded that lymphocytes contain gamma globulin and hence are potential carriers of antibody protein. Ehrlich and Harris<sup>19</sup> and Harris Gumm, Mertens and Ehrlich<sup>20</sup> conducted experiments to show antibody appeared in the efferent lymph of the popliteal lymph nodes of rabbits after local intradermal injection before the rise in serum antibody titer. They also presented evidence<sup>20-21</sup> to show that the antibody was actually contained within the lymphocytes and they concluded that antibody was either manufactured in the cell or was concentrated therein and transported to the blood by the lymphocyte.

These conclusions are in sharp contrast to those reached by Hehtoen in 1911. This investigator followed the rise in antibody titer in dogs after amputation of the leg into which antigen had been injected subcutaneously three to forty eight hours previously and found that the rise was comparable to that in normal controls. These findings would indicate that other sites of antibody formation can fully compensate for any antibody which may have been produced in local areas draining the site of antigen injection, even though the latter have been ablated. They also indicate the rapidity with which antigen was spread throughout the body after the initial injection.

Dougherty Chase and White have presented substantiating evidence for the presence of antibody within lymphocytes.<sup>22</sup> They have also extended the concept of pituitary-adrenal cortical control of lymphoid tissue structure and function to embrace control of antibody release from tissue cells.<sup>23-25</sup> An analysis of the evidence for the concept of adrenal cortical hormonal control of lymphoid structure and function has been the subject of a previous paper<sup>26</sup> and extensive résumé of related work would be unwarranted here. There is little doubt that increased availability of C11 oxygenated adrenal cortical steroids is associated with definite histologic degenerative changes in lymphoid tissue. However, there is marked disagreement concerning the influence of these hormones on the functional capacity of lymphoid tissue. In some animal species adrenal cortical hormone seems to influence the peripheral blood lymphocyte count.<sup>30-34</sup> In other species proof of a specific influence is yet forthcoming.<sup>27-29</sup> And in man there is at present conflicting evidence in regard to the existence of a pituitary-adrenal cortical mechanism for regulating the level of circulating blood lymphocytes. The hematologic picture in patients with Cushing's or Addison's disease<sup>35</sup> suggests a possible relationship between the relative numbers of lymphocytes and the activity of the adrenal cortex. In absolute numbers however, the alterations in lymphocytes are not as striking as the differences in the polymorphonuclear leucocytes and it

is difficult to evaluate the nonspecific secondary effects associated with the general metabolic disturbances in such conditions. In the hands of some investigators<sup>36</sup> a significant lymphopenia has been found to occur in patients with normal adrenal function after the administration of adrenocorticotrophic hormone. Others<sup>37</sup> have not observed any hematologic alterations specifically referable to a direct action of adrenal hormones on lymphoid tissue. No increment of serum gamma globulin or augmented antibody response has been found to follow the administration of adrenocorticotrophic hormone in human beings, as reported by Dougherty and White<sup>38</sup> in animals.

The influence of adrenal cortical hormones on the rate of production of lymphocytes by lymphoid tissue is also controversial. Some workers<sup>38-39</sup> have reported a significant reduction in the number of thoracic duct lymphocytes produced per unit of time after administration of pituitary adrenotropic hormone. Data collected in this laboratory failed to show any significant effect of adrenal cortical hormone on the rate of production of lymphocytes in normal and adrenalectomized cats.<sup>29</sup>

In spite of the lack of conclusive data concerning the influence of adrenal cortical hormone on the productive capacity of lymphoid tissue, considerable evidence exists to suggest that alterations in availability of adrenal cortical hormone are of importance in the immunologic response of animals.<sup>20, 28</sup> Dougherty and co-workers have reported an appreciable augmentation of serum antibody titer in mice by injections of adrenal cortical hormone or by exposure of the animals to various noxious stimuli designed to promote increased hormonal secretion by the adrenal cortex, such as roentgen radiation.<sup>40, 41</sup>

Other investigators have not all been able to demonstrate the potentiating influence of adrenal cortical hormones on antibody formation. Experiments performed in this laboratory in connection with the effects of x-ray on immunologic processes in rabbits<sup>42</sup> failed to show any alteration in the level of serum antibody by exposure to either small or large doses of x-ray, in spite of marked destruction of lymphoid tissue. Eisen and associates,<sup>43, 44</sup> using quantitative serologic methods, could detect no alteration in serum globulin or antibody as a result of alterations in availability of adrenal cortical hormone in mice. Houghton and co-workers<sup>45</sup> could not find any impairment of the response of cats to antigens by adrenalectomy, and Murphy and Sturm<sup>46</sup> obtained data which suggested an actual augmentation of the immune response following the procedure. It is therefore apparent that opinion differs in regard to the hormonal control of antibody release from lymphoid tissue.

#### RATIONALE OF EXPERIMENTAL APPROACH

The purpose of the present work can be summarized under three headings. First, an attempt has been made to repeat under different experimental conditions the work of previous investigators insofar as the presence of antibody protein in lymphocytes is concerned. Second, we have studied the influence

of sudden extensive destruction of lymphoid tissue during the early phases of antibody production upon the antibody content of the lymph and blood serum. The tool used for this destruction was massive total body roentgen irradiation. Third in extension of this latter phase of the experiment was the study of the effect of large doses of adrenal cortical extract on the antibody content of thoracic duct lymph. Previous experiments had failed to show any significant effect of the administration of adrenal cortical hormone on the numbers of cells in thoracic duct lymph in cats. Consequently experiments on the effect of hormone administration have not represented one of the main features of this investigation. However a limited amount of data was collected pertaining to the influence of large doses of adrenal cortical extract on antibody content of lymph and this has been included in this report.

### *Experimental Procedure of Immunization, Cannulation and Lymph Collection*

The experimental animal used throughout was the cat. A standard antigen of typhoid vaccine (1 000 million killed organisms per cubic centimeter) prepared by the New York State Department of Health Laboratories was used for immunologic purposes. Blood samples were withdrawn prior to immunization. Each cat was given 0.2 cc vaccine subcutaneously followed by a similar amount intraperitoneally the next day. Four days after the first injection the cat underwent thoracic duct cannulation. This time interval was chosen because it was advisable that the studies should be undertaken during the early stages of antibody formation. Harris and co-workers<sup>2</sup> found that in their hands the maximal differences between cell antibody titer and that of the lymph and serum were detected around four to five days after inoculation. All cats used showed a definite serum antibody titer at this time.

Cannulation was performed under pentobarbital sodium anesthesia using the same operative technique as previously described. Lymph was allowed to flow freely from the small glass (silicone coated) cannula into a graduated 15 cc centrifuge tube containing a small amount of 1 per cent sodium heparin in saline. Care was taken to prevent contamination of the lymph by blood or serum and any specimen so contaminated was discarded. Hydration of the animals was maintained by subcutaneous injections of isotonic saline in amounts of approximately double that lost as lymph. The lymph collected was then subjected to the studies to be described.

### *Experimental Procedure to Demonstrate the Presence or Absence of Antibody in Lymphocytes*

I — After immunization, each of the six animals in Group I was subjected to thoracic duct cannulation. Lymph was collected as a single volume for the entire period of lymph drainage (five to seven hours). The lymph was then centrifuged until all the cells had been removed from the supernate. A specimen of this cell free lymph was stored in the frozen state for titration.

The packed lymphocytes were resuspended in a volume of heparinized saline approximately equal to the original volume of lymph and recentrifuged. This washing process was carried out three times in large volumes of the heparinized saline care being taken with each washing to break up gently the clumps of lymphocytes so that they would be washed free of any lymph fluid. The final fourth washing was performed with approximately 14 cc of saline in 15 cc centrifuge tubes. A specimen of this last washing fluid

after centrifugation was preserved for titration. The total volume of fluid was then reduced to 125 cc, and the packed, washed cells in the bottom of the tube were resuspended carefully in this small volume. Cell counts and smears were made on this suspension after mixing. It was not possible in every instance to separate completely all clumps of lymphocytes by agitation before counting. In such cases, the counts must be regarded as only rough approximations. Nevertheless, it can be observed from Table I that all suspensions were extremely cellular, the lowest total count per millimeter<sup>3</sup> being 47,000 cells and the highest 178,500 cells. Smears made from the suspensions showed good preservation of lymphocyte morphology in all cases and revealed that lymphocytes comprised almost the total number of cells in each suspension. After counts were obtained, the cell suspension was again centrifuged, and the supernatant saline removed. One cubic centimeter of distilled water was added to the packed washed lymphocytes, and partial lysis of the lymphocytes resulted.

Before titrations were carried out, both the specimen of cell free lymph and the suspension of lymphocytes in distilled water were subjected to alternate rapid freezing and thawing six times, employing a dry ice acetone solution as the freezing media. Both cell free lymph and the lymphocyte suspension were similarly treated in order to eliminate any possible effect of the procedure or antibody protein as a source of difference between the titers of the two. After lysis in this manner, the remaining emulsion was subjected to centrifugation to remove the particulate cell stroma which would render performance of agglutination tests difficult. Titrations were then carried out (Wadsworth<sup>4</sup>) on the cell extract, the cell free lymph, the final washing fluid, and on serum collected before immunization, at the onset of cannulation and at the end of the experiment. Standard "H" (flagellar) and "O" (somatic) antigens prepared by the New York State Department of Health Laboratories were used. The first dilution of cell extract, lymph, or serum was 1 to 10 for this series of titrations. Subsequent dilutions progressed by double in each tube. The tubes were incubated at 37° C for twelve to eighteen hours. The wide variation of serum antibody titer from animal to animal is indicative of the individual differences in the degree of immunologic response.

*Results* As shown in Table I, in none of the six cats included in Group I was it possible to detect antibody in extracts of rich suspensions of washed lymphocytes. Each animal, however, had a demonstrable antibody titer in both the blood serum and lymph fluid at the time of cannulation. In two instances (Cats 694 and 712) the blood serum was found to contain agglutinating substances for typhoid "O" antigen prior to experimental immunization. These two animals probably should not, therefore, be regarded as comparable to the larger group. Nevertheless, in no instance no matter what the titer of antibody in the blood serum or lymph, was any antibody found within the extract of lymphocytes.

It will be noted that in almost every instance the titer of the cell-free lymph fluid was slightly lower than that of the blood serum. The absence of any titer in the final washing fluid demonstrates that any detectable amount of antibody had been washed free of the lymphocytes by the procedure. It will also be observed that in three instances there was a significant rise in serum antibody concentration during the course of thoracic duct drainage. The possible importance of this rise will be discussed later.

The completely negative titers in the extracts of these highly cellular lymphocyte suspensions indicate the lack of titrable antibody within the lymphocytes as studied under the conditions of the experiment.

TABLE I. COMPARATIVE TITRATIONS OF SERUM CELL FREE LAMIN AND EXTRACTS OF PIGEON, WASHED LAMINOCYTES IN A STUDY OF THE ANTIBODY CONTENT OF LYMPHOCYTES

\*Figure represents lymphocytes per cubic millimeter in 1 cc of cell-rich lymph

II—In the following experimental approach, the repeated washing and handling of the lymphocytes was eliminated, excluding this as a possible source of loss of lymphocytic antibody protein during the procedures. The lymph from each cat was collected in two hourly volumes, and the amount of each specimen recorded. After thorough mixing of the lymph for five minutes, duplicate cell counts were made and the specimen then was centrifuged. Approximately 1 cc samples of the supernatant, cell free lymph were withdrawn. The remaining volume of the supernate was reduced to about 1 cc by pipetting off the excess cell free lymph. The packed cells in the bottom of the centrifuge tube were resuspended and thoroughly mixed in the remaining 1 cc of lymph fluid for five minutes. White cell counts were made from this specimen to determine the cell concentration and a smear was made to study the cellular morphology. In each case lymph was collected and handled in this fashion every two hours for the duration of the experiment. Blood specimens for titration were obtained just before cannulation and at the completion of the experiment.

As in the previous experiment, the lymph in each specimen collected for titration was alternately frozen and thawed six times. The cell free and cell rich specimens were each subjected to this procedure in order to eliminate alteration of antibody by the lysing process as a possible source of any significant difference in antibody titer between the two. In most instances the cell rich lymph contained a gelatinous residue after lysis of the cells and this was removed by a stirring rod. Titrations against standard "H" and "O" antigens were then carried out for each specimen and were read the next day (twelve to eighteen hours later).

Every cat used showed a low but detectable serum antibody titer at the time of cannulation. This titer varied widely from animal to animal, thus indicating that each animal was individual in the rapidity with which its immunologic mechanism responded to the antigen. However all must have been in the initial phases of antibody production since the time elapsed from the onset of immunization was so short. No attempt was made to compare the antibody responses of different cats each animal representing a distinct experiment.

**Results** The animals used for this phase of the experiment are included in Groups II and III. The data collected are presented in Tables II and III. Comparative antibody titrations were made between the cell free and lysed cell rich fractions of fifty seven separate specimens of lymph. Since titrations were made against both typhoid 'H' and typhoid 'O' antigens, this represented a total of 114 comparisons between the antibody content of cell free lymph and that of the lysed cell rich fraction of the same specimen. Of this total number of comparative titrations there was no significant difference between the antibody concentration of cell rich and cell free lymph specimens except in five instances. In three of these the antibody titer was higher in the cell free lymph than in the lymph which had been rich in cells before lysing. It is apparent, therefore that in only two instances did the lysed cell rich specimen contain significantly more titrable antibody than the cell free lymph plasma. In view of the small percentage of comparisons indicating a higher concentration of antibody in the cell extract and the roughly equal percentage of comparisons yielding the opposite results it is quite apparent that no valid evidence of the presence of antibodies within the thoracic duct lymphocytes was obtained in these experiments.

It is interesting to note the extremely high lymphocyte concentration in some of the specimens examined. Thus one special collection (not included in Table II) contained 550,000 cells per millimeter<sup>3</sup> of lymph. The antibody titer of this sample after lysing of the cells was "H" 1/160 and "O" 1/320. The titer of the cell free portion of the same collection was "H" 1/80 and "O" 1/640. It is evident that no significant difference in antibody concentration existed between the two samples of lymph. Other cell rich specimens were obtained one with a count of 311,000 lymphocytes per millimeter<sup>3</sup> and

six with concentrations from 100,000 to 200,000 cells per millimeter<sup>3</sup>, and seventeen with counts between 40,000 and 100,000 per millimeter<sup>3</sup>. In no instance was the antibody concentration of any of these cellular lymph suspensions higher than that of the cell-free supernate from the same lymph collection. These data are included in Tables II and III.

In addition to the twelve animals included in Groups II and III there were three animals who were subjected to the same procedure but were not included for analysis. The results obtained from one cat were excluded because the presence of a specific serum antibody titer before immunization did not conform with the negative preimmunization titer for the other animals. Another experiment was discarded because all the titrations with typhoid "O" antigen were overgrown with *Bacillus pyocyaneus*. A third animal failed to develop a detectable antibody in the lymph. It is noteworthy in regard to this animal, however, that the serum antibody titer was positive at the onset of cannulation ("O" 1/20) and rose significantly during the period of lymph drainage ("O" 1/80 at end of experiment). In spite of this, no antibody could be detected in any of the lymph specimens throughout the day. Two other animals were studied for an insufficient period of time to be included in the group for analysis. One of these had been hyperimmunized with typhoid vaccine prior to cannulation and demonstrated a high antibody titer of equal degree in both serum and lymph.

None of these animals yielded any results which conflicted with those included in Tables II and III. Thus, in no instance were the data indicative, or even suggestive, of the presence of more antibody in the lymph containing extracts of lymphocytes than in the cell-free lymph.

#### *The Effect of Massive Whole Body X-ray on the Antibody Content of Lymph*

The animals included in Group II each were exposed to 1,500 whole body x ray two hours after cannulation, a preliminary lymph sample for base line determinations having been collected as described. The irradiation was delivered at 250 KVP at 15 Ma through aluminum parabolic plus 1/2 mm copper filters, the output being 28 r per minute and the

target distance twenty-two inches to the center of the cat. This amount of x-ray is much greater than the lethal range for cats and was chosen so that there would be no doubt that a maximal destruction of lymphoid tissue had been accomplished.

Lymph specimens were collected every two hours for eight hours after x-ray and handled as described previously. At the end of this time blood was collected for antibody titration and the animal sacrificed. This amount of x-ray causes a fairly uniform and progressive fall in thoracic duct lymphocytes over the eight-hour period, so that the specimens collected toward the end of the experiment usually had a low lymphocyte content.

**Results**—The massive whole body roentgen radiation to which these animals were exposed was given with the intention of destroying large numbers of lymphoid cells over a short period of time. If lymphocyte precursors susceptible to damage by roentgen radiation contain significant antibody protein, sudden extensive destruction of large numbers of these cells should result in a sharp rise in the antibody concentration of the lymph fluid. Since thoracic duct lymph normally contains relatively large numbers of cells, almost all of which are of the lymphocytic series, such a phenomenon should be more easily demonstrable in lymph than in the blood.

In every case the lymphocyte content of the lymph fell progressively after exposure to x-ray. This fall is a result of the destructive action of x-ray on lymphoid tissue with impairment of lymphocyte production. An analysis of the effect of x-ray on the rate of lymphocyte production has been the subject of another report<sup>48</sup> from this laboratory and will not be discussed here. Suffice it to say that the marked impairment of lymphocyte production is a reflection of degenerative changes brought about in lymph nodes by roentgen radiation.

In spite of the widespread destruction of lymphoid cells, no appreciable alteration in antibody concentration of the lymph was detected. Thus, two hours after exposure to x-ray, the antibody concentrations of both cell-free and cell-rich lymph specimens were approximately the same as those of cell-free and cell-rich lymph before x-ray for every animal except one (Cat 608). In this instance the "O" titer of the cell-free lymph fell from 1/320 to 1/40 after x-ray. Such a reduction in titer is just the opposite of the theoretical response one

would expect if the damaging influence of x-ray were causing a release of antibody protein from the lymphocytes into the surrounding lymph. Titrations at the end of four hours were also approximately the same as before x-ray in all animals except Cat 582, which showed a positive "O" titer of  $\frac{1}{40}$  in the cell-free lymph at this time, whereas before x-ray no titer was detected. As shown in Table II, three of the animals (Cats 608, 549, and 582) showed a tendency for the lymph antibody titer to rise toward the end of the eight-hour period following x-ray. All the other animals showed no appreciable alteration in lymph

Fig 1—Graphic representation of the comparative antibody concentrations of cell-free and cell-rich lymph in nine cats; the lymph specimens being collected every two hours. The values for lymphocytes represent the average number of cells in each two-hour lymph specimen per millimeter<sup>3</sup>.

antibody titer from the beginning to the end of the experiment. Fig 1 shows the reduction in the average numbers of lymphocytes in thoracic duct lymph after exposure to x-ray and the slight rise in average antibody titer of both cell-free and cell-rich lymph over the ten-hour period of thoracic duct lymph drainage. The significance of the slight rise in lymph antibody titer in three animals is not apparent. If it were the result of release of immune globulins from lymphocytes into the lymph fluid following x-ray, one would expect a more consistent and distinct elevation in the lymph of all, or at least most of the animals. Thus, in the experience of Dougherty and White<sup>12</sup> exposure of mice to x-ray was followed within two to three hours by a sharp and impressive rise in serum antibody titer. It is evident that in no single animal in this group was there a sharp rise in lymph antibody titer of any appreciable degree. In the three instances in which a significant rise in antibody titer after x-ray was

observed the greatest elevation was never more than two tubes (doubling the dilution in each tube). Conceivably the rise may have been due to hemorrhagic changes in the lymph nodes with diffusion of serum antibody protein into the lymph spaces. Or perhaps the protein concentration of the lymph became higher toward the end of the experiment in spite of water and electrolyte replacement. It is also possible since lymph fluid is derived from the extra vascular fluid that the rise in lymph titer like the rise in blood serum titer during the period of the experiment was not related to the lymphoid structures at all. Since these various possibilities were not controlled the mechanism of the slight antibody rise in the lymph of these three cats cannot be evaluated accurately. Lymphoid tissue destruction with release of antibody into the lymph is a possible explanation. However in view of the lack of consistent elevation of antibody titer in spite of extensive lymphoid tissue destruction in all cases the relative importance of such a mechanism in bringing about an increment in antibody concentration seems negligible.

The blood serum antibody titer rose significantly during the period of cannulation (ten hours) in four instances (Cats 641 657 643 and 676) or in exactly 50 per cent of the animals. The mechanism of this antibody increase in the serum in spite of the removal of the major portion of all lymph contents and the functional ablation of all lymphoid tissue by x-ray is of considerable speculative interest. This will be considered further in the discussion of the results. It will be noted that in one instance (Cat 608) there was a significant decrease in the serum antibody titer against typhoid "O" the explanation for which is not apparent.

No consistent correlation was found to exist between the height of the serum antibody titer and that of the lymph. Thus in several instances no antibody could be detected in the lymph in spite of a significant serum antibody titer. The concentration of serum antibody at the end of the experiment was higher than that of the lymph in all cases except one (Cat 549).

#### *Experimental Procedure to Demonstrate the Effect of Adrenal Cortical Hormone on the Antibody Content of Lymph*

The animals in Group III each were given 25 cc of aqueous adrenal cortical extract (Upjohn) subcutaneously two hours after the onset of cannulation. No attempt was made to administer adrenal cortical extract per kilogram of body weight. However the amount given was much more than that previously reported as required for maximal effect on lymphoid tissue. Lymph was collected in two hourly volumes after the hormone injection and treated as in the case of those animals exposed to x-ray. Serum for titration was obtained at the beginning and end of cannulation.

*Results*—The failure of adrenal cortical hormones to influence the rate of production of thoracic duct lymphocytes in cats has been previously demonstrated. As indicated in these previous experiments a fall is noted in the numbers of lymphocytes delivered via the thoracic duct per unit of time in normal untreated animals as a result of the procedure of cannulation itself. This initial fall is unrelated to adrenal cortical activity since it was shown to occur in animals previously adrenalectomized irrespective of whether or not

adrenal cortical hormone was administered. In the present series the same decline in the total lymphocyte content of lymph per unit of time after cannulation was noted but was not felt to be a result of adrenal cortical hormone administration.

It is apparent that in this limited series of experiments administration of adrenal cortical extract in large amounts had no effect upon the relative antibody concentration in cell free and cell-rich lymph. In no instance was a significant rise in the antibody titer of cell-free lymph found to occur within six hours after hormone injection. Three to six hours is the time interval after hormone administration for maximal effect on lymphoid tissue and antibody titer, as reported by previous investigators<sup>20</sup>. In one instance (Cat 584) a rise in lymph antibody titer at the end of the experiment was recorded. The mechanism of this rise, as in the case of the three irradiated animals who demonstrated the same phenomenon, is not completely clear. Here again it may have been the result of release of immune globulins from the cytoplasm of lymphocytes, but the possibility that other factors, previously discussed, may have entered into the picture cannot be excluded.

In two instances (Cats 584 and 650) a detectable serum antibody titer for typhoid "H" antigen was present although a negative lymph antibody titer was recorded. Also in two of the four animals of this group, a significant rise in serum antibody titer during the period of lymph drainage was recorded.

It should be re-emphasized that none of the comparisons of cell-free and cell-rich lymph in this group of animals revealed any higher antibody concentrations in the cell-rich fraction. It will be noted that there were relatively more specimens which were highly cellular for each animal in this group than in those exposed to x-ray.

#### DISCUSSION

It was the purpose of these experiments to study some of the features of antibody production by lymphoid tissue and its transport to the circulating blood by lymphocytes. It was recognized that the experimental approach differed from any employed in previous investigations of this nature. However, if the formation of antibody by lymphoid elements and the transport of antibody to the blood by lymphocytes represents a major factor in the total immunologic response of the animal, the technique used in these experiments should provide a valid means to study these phenomena. Thus, collection of all the lymphocytes and lymph draining from areas presumed to be participating in immune globulin production should yield detectable antibody in extracts of these lymphocytes, if they represent a major source of transport of antibody into the circulating blood. The thoracic duct represents the final main stream for the flow of lymph after the entrance of lymphatic tributaries from all regions of the body below the diaphragm. Since the antigen injections were intraperitoneal and into the subcutaneous area of the back it is apparent that at least part of the total lymph collected was draining from lymph nodes concerned in the uptake of antigen. The lymphocytes originating in this nodal tissue would presumably contain antibody

The absence of any detectable antibody in the extracts of concentrated suspensions of washed lymphocytes collected during a period of active antibody production can be interpreted only as indicative of the very low or negative titrable antibody content of lymphocytes as measured in these experiments. The negative results obtained by this technique were substantiated by the large number of comparisons of relative antibody content of cell free lymph fluid and lymph containing many lymphocytes which had been artificially lysed in order to release their contents into the lymph fluid.

It is not readily apparent why the experimental approach used should yield negative results in view of the positive findings of others in studies on the crude extracts of minced lymph nodes as well as on the lymphocytes collected from a single lymph node during the site of antigen injection. The conflicting data may perhaps be partially explained by differences in experimental techniques. There are possible objections to these and other experimental methods which merit critical evaluation. For instance it might be argued that the method of cell lysis employed resulted in antibody remaining in some manner inalterably bound to cell stroma and incapable of appearing free in the fluid lymph. Such argument appears negated by the fact that similar technique has been employed with positive results in experiments by other investigators. It is also conceivable for example, that the amount of antibody protein within each lymphocyte may have been so small that detection would be difficult simply on the basis of the range of antibody concentration. This possibility was counteracted as adequately as possible by studying the antibody content of very large numbers of washed lymphocytes suspended in a relatively small volume of fluid. Under these conditions, detection of any antibody, even of low titer would be considered significant evidence of the presence of antibody within lymphocytes. On the basis of experiments by previous investigators in which high concentrations of antibody were found in extracts of washed, minced lymph node tissue, it was anticipated that the demonstration of significant amounts of antibody in cell rich suspensions would not be difficult. The complete absence of titrable antibody in any of these suspensions, however indicated that the presence of antibody within lymphocytes could not be detected by this technique. It was realized that even small amounts of antibody in each lymphocyte entering the blood would be significant because of the rapid turnover of these cells and the processes of body metabolism which conserve serum protein. Thus repeated contributions of antibody however small, if sufficient in number would ultimately result in substantial titers. It can be stated however, that under these circumstances detection of such small amounts of antibody in cells would be rendered very difficult by any approach.

There also is the possibility that the antibody protein within lymphocytes may exist in an incomplete form which has not developed specificity. In such an event detection by specific immunologic titration would be impossible. This contingency, which is not supported by any evidence, has not been circumnavigated by any method yet employed.

It may also be argued that antibody was not found in extracts of lymphocytes in these experiments since perhaps only a certain percentage of lymphocytes collected were produced in areas concerned with the initial uptake of antigen and subsequent antibody production. Following this line of reasoning, a small amount of antibody protein in some of the cells may have been obscured by the contents of other cells not transporting antibody. Such a possibility cannot be completely excluded. Nevertheless, as previously stated, it is likely that a large number of lymphoid areas participated in the uptake of antigen and that the products of these nodes entered the thoracic duct system. These lymphoid areas were presumed to be actively producing antibody at the time of cannulation. It would seem probable, if antibody formation by lymphatic tissue and transport to the blood by lymph represents a major factor in the elevation of serum antibody concentration that collection of all thoracic duct lymph and its contents for a several hour period during the stage of active antibody production would yield significant amounts of titrable antibody.

Species difference may conceivably have accounted for the negative results in cats as contrasted to the positive findings of previous investigators in mice and rabbits. The possibility that lymphoid tissue varies in its functions from one mammalian species to another can be clarified only by further investigation. The only conclusion reached from these experiments is that demonstration of antibody within lymphocytes of the cat was not possible using a technique basically similar to that employed by previous workers in different species.

The continued rise in serum antibody titer in eight of the animals during the course of thoracic duct damage casts further doubt upon the necessity of lymphatic transport of antibody for the development of high serum antibody levels. The possibility exists that antibody protein formed within lymph nodes may have entered the blood stream directly through the vascular system of the nodes themselves. Diffusion of protein across capillary endothelial membranes from lymph is not thought to occur<sup>3</sup> and consequently actual intravascular production of antibody in lymphoid areas would seem necessary in this event. The concept under question, however, deals with antibody formed in lymph nodes and transported to the blood stream by the lymphocytes produced in the same area. The normal route of entrance of lymphocytes into the circulating blood is via the lymphatic system<sup>1, 2, 3</sup>. It is apparent that removal of practically all lymph before its entrance into the circulating blood eliminated lymphatic transport of antibody from any lymphoid tissue draining into the ductile system as a contributing factor in the subsequent rise of serum antibody concentration. However, it is appreciated that not all entrances of lymph into the circulating blood were blocked in these experiments. In performing the operation, small tributaries from the head and left foreleg were usually ligated. Small ducts from the right foreleg, head, and thorax may have had separate channels of entrance into the blood. However, not more than a small percentage of the total lymphoid tissue of the

body could have returned access to the blood through the normal channels and these few areas must have been relatively far removed from the site of antigen injections. If it is maintained that the increase in serum antibody titer after cannulation was due to the continued production of antibody by this small amount of lymphoid tissue whose products still had access to the blood by the lymphatic route then several observations are apparent which conflict with the concept of antibody formation by local lymphatic tissues. First it would be necessary to concede that antibody production had rapidly become a generalized process taking place in all lymphoid tissue rather than primarily in that tissue concerned with the uptake of antigen. Second the rate of antibody formation by this small amount of lymphoid tissue with an available lymphatic entrance into the blood would have to be very great and the concentration of antibody within the lymphocytes transporting it to the blood would necessarily be quite high. The possibility that the elevation in serum antibody could have depended upon the small amount of lymph still having access to the blood seems particularly remote in those experiments in which animals were subjected to heavy whole body irradiation. It seems reasonable to conclude little likelihood exists that the observed rise in serum antibody titers can be explained by such a mechanism.

There are other factors which may have been responsible for the continued rise in serum antibody in spite of removal of most of the lymph contents and cessation of antibody formation by lymphoid tissue. Thus, the rise may have been due to (1) continued immune globulin production by some tissue more radioresistant than lymphoid cells and not dependent upon lymphatic transport of its products to the circulating blood, (2) release of preformed antibody directly into the blood stream or (3) marked hyperglobulinemia as a result of hemoconcentration with a concomitant increase in antibody concentration per unit volume of serum without an actual rise in the total amount of circulating antibody. An attempt to combat this latter factor was made by parenteral administration of isotonic saline solution in amounts about double the volume of lymph lost. It is therefore improbable that hemoconcentration was of great importance in the elevation of serum antibody.

The relative importance of the first two mentioned mechanisms is of course, hypothetical. The data would indicate that release of significant amounts of antibody protein from cells of the lymphoid series does not occur even after massive roentgen radiation. Whether some other type of cell might release antibody protein into the serum when damaged by x-ray can not be judged from these experiments. That antibody production in rabbits can go on after lymphoid tissue has been severely damaged was indicated in previous experiments performed in this laboratory.<sup>1</sup> Thus exposure of the animals to large doses of x-ray five days after immunization failed to alter in any way the rate or degree of antibody appearance in the blood in spite of widespread damage to lymphoid tissue. In view of this evidence it is probable that continued production of antibody by some tissue not immediately

destroyed by x-ray offers the best explanation of the continued rise in the serum antibody in these animals

The exposure of these animals to massive doses of x-ray was based on the assumption that if lymphoid cells contain antibody protein the resulting cell damage would be reflected in alterations in the intracellular and extracellular antibody content. The extreme sensitivity of lymphoid elements to roentgen rays is well known. The amount delivered to these animals was far in excess of that required to cause widespread damage to lymphoid tissue and was used in order that the destruction of this tissue would be unquestionable. Of course, there is reason to believe that mature lymphocytes may be relatively undamaged by irradiation of this degree and that the chief site of damage is the progenitor cells. If the latter contain antibody in any appreciable amount, the extensive cell damage wrought by the x-rays would have released antibody into the surrounding fluid, provided that such a phenomenon can occur after cell destruction. If lymphocytic dissolution, as caused by roentgen irradiation is capable of causing such a rise in serum antibody titer, the phenomenon should, then, be all the more pronounced in lymph. The results, however, fail to show any sharp or distinct alteration in lymph antibody titer after x-ray exposure. It is therefore, unlikely that an increase in serum antibody could be attributed to release of antibody from lymphoid cells. That marked lymphoid tissue destruction had been brought about is evident from the rapid decline in lymphocyte production over the eight-hour period of thoracic duct clamping. The absence of any appreciable augmentation of antibody titer of the cell-free lymph was interpreted as supportive evidence for a lack of titratable antibody within lymphocytes.

The theoretical influence of excessive amounts of adrenal cortical hormones on lymphocytes, according to the concept of pituitary-adrenal cortical control of lymphoid structure and function, would be one of dissolution and degeneration. This lymphocytic dissolution has been stated to release gamma globulin from the cell cytoplasm into the serum, and in the case of the immunized animal, the result is said to be an elevation of the serum antibody titer. The amount of data collected in these experiments in regard to this influence of adrenal cortical hormones on antibody titer is relatively small. However, there was no evidence of any change in antibody titer attributable to hormone injection. The failure of both massive irradiation and the administration of adrenal cortical hormone to influence the lymph antibody titer in cats suggests that more work is necessary in elucidating the role of lymphoid tissue in the immunologic mechanism of different species.

#### SUMMARY AND CONCLUSIONS

1. A review of the existing knowledge of the relationship of lymphoid tissue and the lymphocyte to immunologic processes is presented. Brief analysis is made of the theory of pituitary-adrenal cortical control of lymphoid tissue structure and function.

2 An experimental approach is presented for the study of the antibody content of lymphocytes collected from the thoracic duct lymph of cats. Using the technique described, typhoid vaccine as an antigen, and the cat as the experimental animal, no antibody could be detected within extracts of washed lymphocytes. Comparative titrations of the relative antibody content of lymph fluid free of cells and lymph containing large numbers of lymphocytes which were artificially lysed in order to release their protein content into the surrounding lymph fluid also failed to indicate the presence of any antibody within the lymphocytes.

3 A group of cats was exposed to 1500 r whole body roentgen radiation during the period of thoracic duct drainage. This amount of x-ray is in excess of the dosage required for maximal lymphoid tissue destruction. Lymphocyte production diminished markedly after this procedure as evidenced by the fall in output of thoracic duct lymphocytes. Exposure of the animals to x-ray did not significantly alter the antibody content of the cell free lymph fluid. This is interpreted as indicative of the slight or negligible amount of antibody released from lymphoid tissue by x-ray damage of cells.

4 It was observed that the antibody concentration in the blood serum rose significantly during the period of thoracic duct drainage (six to eight hours) in 50 per cent of the animals. This was true in those animals exposed to x-ray as well as the others. This continued rise in serum antibody titer in spite of lymph drainage, particularly in those animals exposed to x-ray two hours after operation suggests either continued antibody formation by some more radioresistant tissue than lymphoid or release of preformed antibody from cells or tissue spaces directly into the blood without the necessity of lymphocytic transport of antibody.

5 Administration of large doses of adrenal cortical hormones (Upjohn) to a small group of cats failed to cause any significant alteration in the antibody content of cell free lymph fluid.

6 A discussion of the results is presented emphasizing the possible criticisms of the technique used. It is concluded that, under the experimental conditions of the experiments, no evidence for lymphocytic transport of antibody to the blood was found.

destroyed by x-ray offers the best explanation of the continued rise in the serum antibody in these animals

The exposure of these animals to massive doses of x-ray was based on the assumption that if lymphoid cells contain antibody protein the resulting cell damage would be reflected in alterations in the intracellular and extracellular antibody content. The extreme sensitivity of lymphoid elements to roentgen rays is well known. The amount delivered to these animals was far in excess of that required to cause widespread damage to lymphoid tissue and was used in order that the destruction of this tissue would be unquestionable. Of course, there is reason to believe that mature lymphocytes may be relatively undamaged by irradiation of this degree and that the chief site of damage is the progenitor cells. If the latter contain antibody in any appreciable amount, the extensive cell damage wrought by the x-rays would have released antibody into the surrounding fluid, provided that such a phenomenon can occur after cell destruction. If lymphocytic dissolution, as caused by roentgen irradiation is capable of causing such a rise in serum antibody titer, the phenomenon should, then, be all the more pronounced in lymph. The results, however, fail to show any sharp or distinct alteration in lymph antibody titer after x-ray exposure. It is therefore, unlikely that an increase in serum antibody could be attributed to release of antibody from lymphoid cells. That marked lymphoid tissue destruction had been brought about is evident from the rapid decline in lymphocyte production over the eight-hour period of thoracic duct damage. The absence of any appreciable augmentation of antibody titer of the cell-free lymph was interpreted as supportive evidence for a lack of titratable antibody within lymphocytes.

The theoretical influence of excessive amounts of adrenal cortical hormones on lymphocytes, according to the concept of pituitary-adrenal cortical control of lymphoid structure and function, would be one of dissolution and degeneration. This lymphocytic dissolution has been stated to release gamma globulin from the cell cytoplasm into the serum, and in the case of the immunized animal the result is said to be an elevation of the serum antibody titer. The amount of data collected in these experiments in regard to this influence of adrenal cortical hormones on antibody titer is relatively small. However, there was no evidence of any change in antibody titer attributable to hormone injection. The failure of both massive irradiation and the administration of adrenal cortical hormone to influence the lymph antibody titer in cats suggests that more work is necessary in elucidating the role of lymphoid tissue in the immunologic mechanism of different species.

# A STUDY OF CHOLINESTERASE ACTIVITY IN THE BLOOD OF PATIENTS WITH HEMATOLOGIC DISEASE

ARTHUR SAWITSKY, M D, MANUEL ROWEN, M D, AND LEO M MEYER, M D  
NEW YORK, N Y

IT HAS been shown<sup>1 2</sup> that red blood cell cholinesterase and serum cholinesterase are decreased in patients with pernicious anemia in relapse and that the activity of this enzyme returns to normal with the institution of adequate therapy. Glob and associates<sup>3</sup> administered DFP (diisopropyl fluorophosphate) to two patients with pernicious anemia and induced a complete remission with folic acid and liver therapy in spite of sustained suppression of the plasma and red cell esterase activity caused by the daily administration of DFP. Other investigators have noted that the maintenance of low red cell and plasma esterase activity in man<sup>4</sup> and animals<sup>5</sup> following repeated injections of DFP produced no changes in hepatic, renal or hematologic functions.

Many attempts have been made to correlate the enzymic activity of cholinesterase with myasthenia gravis,<sup>6</sup> liver disease,<sup>7</sup> psychiatric disorders,<sup>8</sup> hypertension,<sup>9</sup> the allergic states,<sup>10</sup> and endocrine dysfunction.<sup>11</sup>

Barnard<sup>12</sup> has stated his belief that individual reactivity to a stimulant or mitant with the production of excessive cholinesterase on the one hand, or deficient enzyme on the other, determines the onset and type of pathologic and malignant hematopoietic disease. Davis<sup>13 14</sup> postulates that the presence of low blood cholinesterase and the associated high acetylcholine concentration is the responsible mechanism for pernicious anemia in relapse.

We have accumulated data of the activity of red cell esterase and serum esterase of patients with various types of leucemia, with and without anemia, various primary and secondary anemias, polycythemia, and myelophthisis in a further effort to clarify the role of cholinesterase found in the red blood cell.

## METHODS AND MATERIALS

The cholinesterase activity of whole blood and serum was determined in 101 patients and twenty one normal subjects, adults and children of both sexes and all races. These determinations were made from random samples drawn at odd times of day and night. In all but the polycythemic patients, therapeutic procedures, blood transfusions, and radiation therapy were avoided prior to the blood sampling. The control series of twenty one normal subjects included fifteen subjects previously reported.<sup>15</sup> Values for ten of the eleven patients with pernicious anemia in relapse and nine of the ten patients in remission have been reported.<sup>2</sup>

Venous blood was drawn from the antecubital vein with a dry syringe and needle. Then 5 ml of whole blood were oxalated with anticoagulant mixture (Wintrobe), and 5 ml were collected in a dry test tube and allowed to clot. The hematocrit (Wintrobe) was determined and a complete capillary blood count done. Reticulocyte counts were also made on some of the more anemic patients.

Cholinesterase activity was measured by the method described in a previous report.<sup>16</sup>

Sickle cell anemia	5	10	65	105	26	3.99	9.84

MCV Mean corpuscular volume in cubic microns

MC HB Mean corpuscular hemoglobin in micromicrograms

## RESULTS

The blood of twenty four patients diagnosed as having chronic lymphocytic leucemia was studied. Table II demonstrates the range of hemoglobin (6.5 to 15.0 Gm per cent) and red cell values (2.5 to 6.3 M). In general these patients were in good clinical condition. The bone marrow was infiltrated with great numbers of lymphocytes and the erythroid tissue was reduced in quantity. The mean cell hemoglobin concentration and the mean cell volume were within the normal range. The cholinesterase activity of the serum varied from 0.88 to 3.64 units and reflected the clinical condition of the patient. The mean serum esterase of the entire group was 2.38 units as compared with a normal of 3.22 units. The mean corpuscular esterase activity for the entire group was 8.67 units ( $\times 10^{10}$ ), compared with 7.57 units ( $\times 10^{10}$ ) in the normal. In this group, therefore, despite the presence of a mild anemia the mean cholinesterase activity of the red cell esterase was within upper normal limits.

Blood samples of eleven patients with chronic myelocytic leucemia were studied. Table III shows the range of hemoglobin (4.5 to 13.5 gm per cent) and red cell (1.5 to 5.15 M) values. The general condition of this group was good but these patients were sicker than those with lymphocytic leucemia. The mean corpuscular hemoglobin and the mean cell volume were normal. The activity of the serum esterase varied from 1.00 to 4.62 with a mean value of 2.34 units, which further reflected the general condition of this group. The mean corpuscular esterase activity varied from 4.22 to 11.25 units ( $\times 10^{10}$ ) with a mean value of 6.60. This value is not significantly lower than the normal mean of 7.57 units.

Studies of the blood of seven patients with acute leucemia were made (Table IV). Of these, five were myeloblastic and two, lymphoblastic. The hemoglobin varied from 3.5 to 11.5 Gm per cent and the red count ranged from 1.0 to 4.4 million per cubic millimeter. The serum esterase values were low.

# A STUDY OF CHOLINESTERASE ACTIVITY IN THE BLOOD OF PATIENTS WITH HEMATOLOGIC DISEASE

TABLE IV  
CHOLINESTERASE ACTIVITY OF THE SERUM AND RED CELLS IN ACUTE LEUCEMIA[illegible]

Patients and 6 were diagnosed as having acute lymphoid leucemia the remainder as having acute myeloid leucemia

Three patients satisfying the criteria for a diagnosis of myelophthisic anemia exhibited macrocytosis and a significantly low red cell esterase activity of 5.97 units ( $\times 10^{-14}$ ). The serum esterase was markedly reduced to 1.99 units (Table V).

TABLE 1 CHOLINESTERASE ACTIVITY OF THE SPLEEN AND RED CELLS IN MYELOPHTHISIC ANEMIA

PATIENT	HB (GM / 100 ML.)	PBC ( $\times 10^6$ / CF MM <sup>3</sup> )	PCTC ( $\times 10^3$ / MM <sup>3</sup> )	MCV (CU $\mu$ )	MC HB (GG)	CHOLINESTERASE	
						SERUM (UNITS / ML.)	MEAN CELL (UNITS $\times 10^{10}$ / PEP CELL)
1	7.00	2.0	61	98	34	1.64	6.38

Mean	6.23	1.8		92	34	1.99	5.91
Standard deviation = $\pm 0.35$							

The blood of seven patients with Hodgkin's disease and ten patients with polycythemia vera was studied. In the former group (Table VI) a mild normochromic normocytic anemia was found. The red cell esterase activity 7.60 units ( $\times 10^{10}$ ), compared favorably with normal values. The serum esterase activity 2.64 units was only slightly depressed.

TABLE VI CHOLINESTERASE ACTIVITY OF THE SERUM AND RED CELLS IN HODCKIN'S DISEASE

PATIENT	HB (CM / 100 ML)	FBC ( $\times 10^6$ LIT MM <sup>3</sup> )	MCV (CU $\mu$ )	MC HB ( $\gamma\gamma$ )	CHOLINESTERASE	
					SERUM (UNITS ML)	MEAN CELL (UNITS $\times 10^{10}$ PER CELL)
1	14.0	4.70	87	29	3.88	7.64

In order to study the effect of active erythropoiesis upon cholinesterase activity two groups of patients were tested. In the first group thirteen patients with secondary anemias (Table VIII) of a hypochromic normocytic type exhibited a red cell esterase activity of  $8.94 (\times 10^{-10})$  units as compared with 7.57 in the normal subjects. The serum esterase of these subjects was depressed. Since many of these patients were debilitated this later finding was anticipated. A second group of five patients with sickle cell anemia in relapse (Table IX) was examined. All five showed active reticulocytosis. In all, the mean cell volume and mean cell hemoglobin were above normal. The serum cholinesterase values were normal. The red cell esterase activity however was markedly increased and a mean value of 9.40 units ( $\times 10^{-10}$ ) was obtained.

#### DISCUSSION

Grob, Lilienthal and co workers<sup>1</sup> have recently reported that following the administration of DFP to normal and anemic subjects the red blood cell esterase regenerated at a rate approximating the calculated rate of red cell replacement in the body and was proportional to the number of circulating reticulocytes. The observed daily cholinesterase regeneration rate was 1.2 per cent. This agrees closely with the calculated daily erythrocyte replacement rate of 0.83 per cent which is based on a red cell life span of 120 days. Koelle and Gilman,<sup>4</sup> working with experimental animals observed similar findings. In a study<sup>2</sup> of the cholinesterase activity of patients with pernicious anemia in relapse who were followed into remission, we found that the rise in cholinesterase activity of the whole blood was primarily due to a rise in activity of the red cell itself. We further reported that this increased activity could not be correlated to cell size nor to the presence of reticulocytosis per se. The mean value for any one red cell was found to vary from low values in patients in relapse to above normal values in early remission. Normal values were obtained only seventy to ninety days following the institution of specific therapy.

The present study substantiates our previous report. Nevertheless Table I demonstrates that increases in cholinesterase activity of the red blood cells is noted in those diseased states where increased erythropoietic activity is present, that is, the secondary anemias, sickle cell anemia in relapse, and pernicious

anemia in early remission Table I also shows that there is some increase in the red cell esterase activity of patients with chronic lymphocytic leucemia, although the bone marrow of the majority of these patients was overwhelmingly infiltrated with lymphocytes and the quantity of erythroid tissue markedly reduced The physiologic implication of this is not yet clear

Conversely, those diseases not associated with increased erythropoiesis and those in which erythropoiesis is depressed show significant depression of red cell esterase activity

A variety of liver function tests made from a sampling of patients with chronic lymphocytic leucemia, chronic myelocytic leucemia, pernicious anemia in relapse, and the secondary anemias did not reveal any consistent correlation to the red cell cholinesterase activity The total protein and albumin concentrations of the serum tended to parallel the serum esterase activity

Although we are unable to explain our findings, we feel that the cholinesterase activity of the red cells as measured in the regenerative anemias is not merely a reflection of the immature cells released into the peripheral blood, but is associated in some other manner with increased red cell production

#### SUMMARY

The cholinesterase activity of the serum and red blood cells of 101 patients with various hematologic diseases was studied and compared with values found in twenty-one normal subjects

The red blood cells of patients with pernicious anemia in early remission, sickle cell anemia, and hypochromic normocytic anemias manifested a cholinesterase activity greater than that of the normal erythrocyte

The red blood cells of patients with pernicious anemia in relapse, acute leucemia, and myelophthisic anemia showed depression of cholinesterase activity

Patients with chronic myelocytic leucemia, Hodgkin's disease, and polycythemia vera were noted to have erythrocytes with normal cholinesterase activity

The mean red cell esterase activity of patients with chronic lymphocytic leucemia was increased to a high normal level

The authors wish to acknowledge the many helpful criticisms and suggestions of Dr Howard M Fitch, Department of Therapeutics, New York University College of Medicine

# IN VITRO EFFECTS ON GRAM-NEGATIVE BACTERIA OF STREPTOMYCIN COMBINED WITH PENICILLIN AND/OR SULFADIAZINE

MAJOR EDWIN J. PULASKI AND MAJOR HINTON J. BAKER  
MEDICAL CORPS, UNITED STATES ARMY

THE therapeutic value of streptomycin is now well established in the treatment of many types of infectious disease of gram-negative and acid-fast etiology<sup>1, 2, 3</sup>. More general use of this agent has, however, been curbed by two important limitations: (1) rapid development of microbial resistance to the drug, and (2) toxicity following prolonged administration with full doses.

The studies reported in this communication were designed to find a solution to these limitations, with particular emphasis on drug fastness. The selective overlapping antibacterial spectra of penicillin, sulfonamides, and streptomycin,<sup>4</sup> and the demonstration by Carpenter<sup>5</sup> and others<sup>6</sup> of the suppression of drug-resistant mutants when certain of these agents are used in combination, served as a background. The plan of the investigation included (1) a study of the comparative bacteriostatic action in vitro of streptomycin and of five purified fractions of penicillin against gram-negative bacteria, and (2) a study of the comparative rate of development of streptomycin fastness of gram-negative bacteria (a) to streptomycin alone, to streptomycin in combination with (b) penicillin and (c) sulfadiazine, and (d) to mixtures of all three agents.

## STREPTOMYCIN AND PENICILLIN

*Materials and Methods*—Streptomycin hydrochloride (Merck) and sodium sulfadiazine were obtained in the open market. The purified penicillin fractions F, dihydro F, X, and K were kindly supplied by the National Institute of Health.

Ammonium penicillin F Upjohn, Lot No. 123—BEL—4, 1625 U/mg

Sodium penicillin dihydro F Pfizer, Lot No. 160619, 1610 U/mg

Ammonium penicillin X Commercial Solvents Corporation, Lot No. 150268, 850 U/mg

Sodium penicillin K Pfizer, 7/12/46, 2075 U/mg

A supply of purified crystalline sodium penicillin G, Lot No. 104115, was furnished through the courtesy of Commercial Solvents Corporation.

All agents used in this investigation were prepared on a weight basis by dilution in triple distilled water. The test organisms were maintained on infusion agar under oils and were grown in test broth (Food and Drug Administration) prior to the experiments. The double strength FDA broth employed has the formula: 2 per cent peptone, 1 per cent beef extract, and 0.5 per cent sodium chloride, in water, adjusted to pH 7.2. The single strength broth contains half this concentration.

The procedure of testing was as follows: One milliliter of stock antibiotic solutions progressively diluted in sterile distilled water was added to a series of sterile tubes. The tubes were inoculated with 1 ml. of 1:50 dilution of a six-hour growing culture of the test organism in double strength broth. The end point was read at the lowest concentration showing no turbidity after forty hours' incubation at 37° C.

From the Surgical Research Unit, Brooke General Hospital, Brooke Army Medical Center, Fort Sam Houston, Texas.

Received for publication July 29, 1948.

**Results**—All the bacteria listed in Table I were tested simultaneously to penicillin G and to streptomycin. Because of the limited supply of penicillins only representative members of each species were tested also against the purified fractions F, dihydrio I,  $\lambda$  and K. The readings listed in Table I indicate the highest dilution in micrograms per milliliter of penicillin and of streptomycin which showed no growth at the end of forty hours incubation. For purposes of discussion, cultures completely inhibited by 10  $\mu$ g per milliliter or less of antibiotic are classified as sensitive while all others are classified as resistant.

It will be noted that gram-negative bacteria exhibit a wide variation in degree of sensitivity to the purified penicillins. Generally penicillin G was as effective as or more effective than the  $\lambda$  dihydrio I and F fractions. A constant finding was the relative inferiority of penicillin K in comparison with the other fractions.

All five strains of *Neisseria facialis* and seven of twelve strains of *Brucella*\* were extremely sensitive to penicillin G. The superiority of penicillin  $\lambda$  against *Brucella* over the other fractions is noteworthy: all twelve strains were completely inhibited by 14  $\mu$ g per milliliter or less. This has been shown to be a bacteriostatic effect lasting through 120 hours but not bactericidal at the time of the forty hour reading. Five of eleven *Proteus* strains and five of twelve *Salmonella* strains were inhibited by concentrations below 10  $\mu$ g per milliliter of penicillin G. The remaining *Salmonella* organisms were moderately resistant while all but two of the remaining *Proteus* strains were very resistant. Some strains among the *Proteus* and *Salmonella* species were more sensitive to penicillin G than to streptomycin microgram and microgram and vice versa. The action of penicillins  $\lambda$  and C on *Herthella* is noteworthy. Nine of ten strains were inhibited in the range of 4 to 20  $\mu$ g per milliliter. The tenth strain was very resistant. All but one of ten *Shigella* strains were refractory to 10  $\mu$ g per milliliter penicillin G and this group in general was found to be moderately resistant. *Tscherichia coli*, the *Aerobacter* Friedlander group and *Pseudomonas* species were very resistant to penicillin especially *Pseudomonas*. The survey suggests that gram-negative bacteria show broader range of reaction to penicillin than to streptomycin. The superiority of streptomycin activity over penicillin against gram-negative bacteria was reaffirmed. All nine genera showed strains sensitive to streptomycin, though some moderately resistant strains occurred among *Salmonella*, *Proteus* and, predominantly, *Pseudomonas*.

#### STREPTOMYCIN, PENICILLIN, AND SULFADIAZINE

**Materials and Methods**—The demonstration of wide generic and species variation in sensitivity to penicillin, and of the greater sensitivity of some organisms to penicillin than to streptomycin led to the second phase of this study. This phase was concerned with the effects of combinations of penicillin G, sodium sulfadiazine and streptomycin on the sensi-

\*These *Brucella* were not freely isolated organisms but stock cultures obtained (in order of presentation in Table I) from the following sources: Dr. Schuhardt, University of Texas Nos. 4, 6, 8, 9, 10 and 11; Col. D. Kuhns, 4th Army Medical Laboratory Nos. 1, 3 and 5; and Dr. H. L. Morton, University of Pennsylvania School of Medicine Nos. 1 and 5. Penicillin is bacteriostatic, not bactericidal. Growth is inhibited by the concentrations listed for longer than five days. Addition of penicillin to tubes showing complete inhibition causes regrowth of the organisms; the rate of regrowth being inversely proportional to the concentration of penicillin in which they were exposed.

The object of the first experiment was to determine whether penicillin or sulfadiazine would prevent or delay the emergence of streptomycin fast bacteria. The concentration of penicillin, 15  $\mu\text{g}$  per milliliter, was the constant and the concentrations of streptomycin were the variables. All strains grew freely in broth containing this concentration of penicillin. A parallel experiment was set up to determine whether sulfadiazine, 150  $\mu\text{g}$  per milliliter, would prevent or delay drug fastness to streptomycin when the two drugs were present in combination. Bacteria grew freely in broth containing this amount of sodium sulfadiazine.

B Number of daily transfers in streptomycin to effect drug fastness

\*P Concentration of penicillin 15  $\mu\text{g}/\text{ml}$

†SAD Concentration of sodium sulfadiazine 150  $\mu\text{g}/\text{ml}$

‡P Concentration of penicillin 0.1 to 0.75  $\mu\text{g}/\text{ml}$  (see text)

§SAD Concentration of sodium sulfadiazine 10 to 75  $\mu\text{g}/\text{ml}$  (see text)

The experiments were conducted as follows. Serial dilutions of streptomycin in the range of 256 to 0.5  $\mu\text{g}$  were prepared in 1 ml amounts, and 0.1 ml of the adjuvant solution (penicillin or sulfadiazine) was added to give the desired final concentration. The tubes were inoculated with 1.1 ml of 1:50 dilution in double strength broth of a six hour growing culture of the test organism (estimated three hundred million organisms per milliliter). They were incubated for fifteen to eighteen hours at 37° C and then read. The organisms showing growth in the tube containing the highest concentration of streptomycin were seeded to normal broth and allowed to grow for approximately six hours. The test was then repeated with this culture. This procedure was continued daily until the organisms showed consistent streptomycin resistance. For controls, one series with streptomycin alone was transferred each day until drug fastness occurred. To check the potency of the antibiotics, a test was set up daily with organisms of known sensitivity. Platings at intervals through each series checked for purity of culture.

The object of the second experiment was to determine whether penicillin and streptomycin together with sodium sulfadiazine would prevent or delay the emergence of streptomycin fast bacteria. When both penicillin and sodium sulfadiazine were combined in half the concentration previously employed, in every instance, except that of *Pseudomonas*, there was complete bacteriostasis even in the lowest concentration (0.5  $\mu\text{g}$  per milliliter) of streptomycin. Consequently, the concentrations of penicillin and of sulfadiazine had to be reduced two to eight times to permit growth in the presence of mixtures of the three agents.

Fig 1—Demonstrates the effect of combinations of penicillin and/or sodium sulfadiazine on streptomycin sensitivity and rate of developing streptomycin fastness of *P. vulgaris*. The ordinates show the amount of streptomycin in micrograms per milliliter required to produce complete bacteriostasis when used singly when combined with either penicillin or sodium sulfadiazine and when the three agents were employed together. The number of daily transfers required for streptomycin resistance to occur under conditions of the test is indicated on the abscissa as

**Results**—The results of the *in vitro* effects of combinations of penicillin and sulfadiazine with streptomycin are shown in Figs 1 to 5 and in Table II. As shown in Fig 1 and Table I *P. vulgaris* required 32 and 12  $\mu$ g per milliliter of streptomycin and penicillin G respectively to effect complete bacteriostasis. Six transfers in streptomycin broth were required for the organisms to grow freely in excess of 100  $\mu$ g streptomycin per milliliter. The addition of 15  $\mu$ g per milliliter of penicillin G reduced the streptomycin requirement from 32 to 2  $\mu$ g per milliliter, which represents one sixteenth and one eighth of the individual requirement of the two substances. The penicillin streptomycin combination delayed the time of occurrence of drug resistance from six to thirteen transfers. Sodium sulfadiazine in the amount of 150  $\mu$ g per milliliter reduced the bacteriostatic concentration of streptomycin from 32 to 8  $\mu$ g per milliliter, which is a fourfold reduction. Sodium sulfadiazine however, did not alter the rate of emergence of streptomycin resistant organisms. Penicillin and sodium sulfadiazine combined in one quarter amounts (0.37 and 37  $\mu$ g per milliliter respectively) allowed growth of this organism, but the addition of only 0.25  $\mu$ g per milliliter streptomycin to this combination was completely inhibitory. The combination of penicillin and sodium sulfadiazine in only one eighth the amounts used alone reduced the streptomycin requirement from 32 to 0.5  $\mu$ g per milliliter, a sixty four fold decrease. A synergistic action of these three drugs on this organism is suggested. Moreover with this combination, drug fastness to streptomycin was retarded from six to twenty transfers. It is significant that drug resistance to streptomycin ultimately did occur.

Fig 2—Demonstrates the effects on streptomycin sensitivity and rate of development of streptomycin fastness of *Proteus* OX2 when streptomycin is combined with penicillin and/or sodium sulfadiazine

Fig 2 illustrates the results with a strain of *Proteus* OX2. This culture required 4  $\mu$ g per milliliter streptomycin or 250  $\mu$ g per milliliter penicillin for complete suppression. The organism became fast to 100  $\mu$ g per milliliter after four transfers in streptomycin broth. The addition of 15  $\mu$ g per milliliter of penicillin G reduced the streptomycin requirement from 4 to 1  $\mu$ g per milliliter, in the face of apparent penicillin resistance of the organism. This combination effected no delay in the time of acquired resistance. Sodium sulfadiazine, 150  $\mu$ g per milliliter, reduced the streptomycin requirement from 4 to 1  $\mu$ g per milliliter, and with this combination ten transfers were required to produce a streptomycin-fast culture against four transfers with streptomycin alone. The simultaneous combination of penicillin and sodium sulfadiazine with streptomycin in one-fourth the concentrations used individually also effected a reduction in the streptomycin requirement from 4 to 1  $\mu$ g per milliliter, and delayed development

Fig 3—Demonstrates the effects on streptomycin sensitivity and rate of development of streptomycin fastness of *Proteus X19* when streptomycin is combined with penicillin and/or sodium sulfadiazine

of streptomycin fastness from four to seven transfers. Although this result represents a less impressive effect than that achieved with sodium sulfadiazine and streptomycin, it is emphasized that only one-fourth the concentrations of sulfadiazine and penicillin were used. Concentrations in excess of this, when combined with the 0.5  $\mu\text{g}$  streptomycin per milliliter, caused complete inhibition.

Fig. 3 represents the effects of the various agents on streptomycin sensitivity of a strain of *Proteus* X19. This organism required 16  $\mu\text{g}$  per milliliter streptomycin and greater than 125  $\mu\text{g}$  per milliliter penicillin G individually for complete inhibition. With streptomycin alone, five transfers in sub-bacteriostatic

Fig. 4—Demonstrates the effects on streptomycin sensitivity and rate of development of streptomycin fastness of *Esch. coli* when streptomycin is combined with penicillin and/or sodium sulfadiazine.

concentrations were made before streptomycin fastness to 100  $\mu\text{g}$  per milliliter was attained. The addition of 15  $\mu\text{g}$  per milliliter penicillin G reduced neither the streptomycin requirement nor the number of transfers necessary for resistance to occur. Sodium sulfadiazine effected a reduction of streptomycin requirement from 16 to 2  $\mu\text{g}$  per milliliter and the striking resistance delay from five to forty-three transfers. The mixture of penicillin G and sodium sulfadiazine in the media in one-fourth the individual concentrations reduced the streptomycin requirement again from 16 to 2  $\mu\text{g}$  per milliliter and effected a delay in resistance to streptomycin from five to thirty transfers. In this instance also, the use of concentrations in the mixture in excess of one-fourth each with 0.5  $\mu\text{g}$  per milliliter streptomycin prevented growth.

Fig. 4 illustrates the effects of the combined drugs on *Esch. coli*. Streptomycin 8  $\mu\text{g}$  per milliliter and penicillin G 35  $\mu\text{g}$  per milliliter individually completely inhibited this organism. In streptomycin broth, thirteen transfers were

made before the culture showed consistent growth in 100  $\mu\text{g}$  per milliliter. The addition of 1.5  $\mu\text{g}$  per milliliter penicillin G caused neither reduction of streptomycin requirement nor delay in acquired resistance. Sodium sulfadiazine 150  $\mu\text{g}$  per milliliter caused no decrease in initial streptomycin requirement but effected a delay in acquired resistance from thirteen to twenty eight transfers.

Fig 5—Demonstrates the effect on streptomycin sensitivity and rate of development of streptomycin fastness of *Ps aeruginosa* when streptomycin is combined with penicillin and/or sodium sulfadiazine

One half these amounts of penicillin G and sodium sulfadiazine with 0.5  $\mu\text{g}$  per milliliter streptomycin allowed no growth. When one fourth the individual concentrations were used together, the streptomycin needed for complete inhibition was reduced from 8 to 4  $\mu\text{g}$  per milliliter and resistance was delayed from thirteen to twenty four transfers.

Fig 5 demonstrates the effects of combined antibacterial agents on *Ps aeruginosa*. This strain required 16  $\mu\text{g}$  streptomycin per milliliter and 5 000  $\mu\text{g}$  per milliliter penicillin G individually for complete bacteriostasis. With streptomycin alone, six transfers occurred before resistance was acquired. Penicillin

15  $\mu\text{g}$  per milliliter had no effect on the necessary initial concentration of streptomycin nor rate of emergence of resistance. Sodium sulfadiazine 150  $\mu\text{g}$  per milliliter reduced the initial streptomycin requirement from 16 to 8  $\mu\text{g}$  per milliliter and delayed resistance from six to eight transfers only. However, when one-half the concentrations of penicillin G and sodium sulfadiazine used individually were combined with streptomycin, there was a delay in acquired resistance from six to fourteen transfers. When the combination of these three drugs was tested in the same manner against eight additional strains of *Pseudomonas*, similar results were obtained with five. Three strains initially resistant to streptomycin evidenced no effect by the addition of the other agents within the range of the experiment.

#### DISCUSSION

Restudy of the action of penicillin on gram-negative bacteria was basic to investigation of the possibility of suppressive effects when the antibiotic was combined with streptomycin. The susceptibility to penicillin G and X of *Neisseria*<sup>9</sup> and *Hemophilus*<sup>10a</sup> is well known. Survey of nine other genera of gram-negative organisms indicated that *Alcaligenes* and *Brucella*, in the main, were moderately sensitive. *Eberthella*<sup>10b</sup> was slightly sensitive. On the other hand, *Pseudomonas*, *Aerogenes*, *Friedlander*, *Shigella*, and *Escherichia* were moderately to completely resistant. Several strains of *Proteus* and *Salmonella* were more susceptible to penicillin than to streptomycin, but the action was variable, the reverse also being the case. The greater susceptibility of *Brucella* to penicillin X than to penicillin G may be of practical importance. The consistent inferiority of penicillin K action and the unspectacular action of penicillins F and dihydro F cast doubt on their possibilities as therapeutic agents against gram-negative infections. Penicillin G was consistently the most effective fraction. Combination of penicillin G with streptomycin gave negative results when the concentration of penicillin was less than inhibitory. Only in the case of *P. vulgaris*, which was relatively sensitive to penicillin, was there any effect on the amount of streptomycin necessary for bacteriostasis and on the number of transfers for developing streptomycin resistance. On the other hand, the two antibiotics in combination showed no antagonistic action.

Sodium sulfadiazine added to streptomycin reduced the initial streptomycin requirement two to eight times for four of the test organisms, and the two agents in combination delayed microbial fastness to streptomycin in four out of five instances.

The use of a combination of penicillin, streptomycin, and sulfonamides was first advocated for mixed infections with several species of bacteria. It was also recommended for the treatment of immediately life-endangering infections of uncertain etiology. Successful experiences with combined sulfadiazine streptomycin therapy for brucellosis<sup>3, 11, 12</sup> after failure when each drug was used alone emphasize the possible value of two drugs to control an infection caused by a single bacterial type.

It was noteworthy in these experiments that when penicillin in relatively small amounts was added to the media containing both sulfadiazine and streptomycin, the bacteriostatic concentrations of the latter drugs could be reduced

significantly and retardation in the rate of streptomycin resistance could be effected. There appears to be a penicillin effect not always in evidence when penicillin was used in combination with streptomycin alone. This phenomenon well demonstrates the opportunity for the effective use of relatively small amounts of penicillin against insensitive gram negative bacteria that is when the organisms can be affected only by marginal or partially inhibitory doses of streptomycin and sulfadiazine.

Complete bacteriostasis of the organisms is essential to eradicate infection. Continued multiplication of bacteria in any combination with streptomycin of these antimicrobial agents in subinhibitory amounts will eventually lead to streptomycin fastness. These studies should therefore not be interpreted to indicate that the management of infections requiring combinations of drugs to control them permits economy in the use of the drugs by the reduction of dosages. On the contrary, maximal therapeutic dosages should be initiated and maintained until the optimal therapeutic response has been relieved.

#### SUMMARY AND CONCLUSIONS

There has been reported in this communication a series of *in vitro* studies concerning the effect of streptomycin combined with penicillin or sulfadiazine or both against gram negative bacteria with special emphasis on the development of drug resistance.

1 The gram negative organisms tested show greater variation in sensitivity to penicillin than to streptomycin. The *B. coli* are very sensitive *in vitro* especially to penicillin. The order of sensitivity for the other genera is as follows: *Aerobacter*, *Escherichia*, *Salmonella*, *Proteus*, *Shigella*, *Pseudomonas*, *Aeromonas*, *Friedlander* and *Pseudomonas*. The action of penicillin is bacteriostatic not bactericidal.

2 Streptomycin in combination with penicillin and sulfadiazine is optimally bacteriostatic for gram negative bacteria and these drugs in combination delay the emergence of drug fast cultures.

3 These studies suggest that in addition to the use of combinations of penicillin, streptomycin and the sulfonamides for mixed infections caused by several species of bacteria, such combinations may also be useful for infections caused by a single etiological agent. Some clinical evidence to this effect already exists.

4 It is essential when these combinations are employed, that maximal therapeutic doses of the drugs be initiated and be maintained until the optimal therapeutic response has been effected. Economy by reduction of dosage is not indicated and may give rise to drug fastness.

# I MUMPS VACCINE

## STUDIES ON HUMAN VOLUNTEERS

HISCAH H MUNIZ MD HORACE M POWELL, SC D, AND  
CLADI G CLIBERTSON MD  
INDIANAPOLIS IND

THE ever increasing demand of physicians and the American public for additional immunizing vaccines against the common virus diseases has stimulated investigation and development of a new specific vaccine. The work presented herein concerns the virus which causes mumps. Original immunization investigation was carried out with live virus or attenuated cultures as vaccines.<sup>1</sup>

Since the first studies by Johnson and Goodpasture in 1934,<sup>2</sup> and the isolation of a filterable cytotropic virus with a predilection for the parenchymal cells of the pituitary, several attempts have been made to perfect a suitable immunizing product. In March, 1947, an editorial in the Journal of the American Medical Association brought the improved mumps vaccine of Enders and co workers from the realm of the experimental journals.<sup>3</sup> It placed the possibility of the development of an adequate immunizing vaccine before the practitioners who would have the opportunity to use this vaccine on a large scale.

Recently an entire issue of the Journal of the American Medical Association was devoted to reviews and reports concerning the viruses and the virus diseases, however, little mention was made of any recent advance in active immunization in mumps. Schultz in his discussion of the present status of viruses and virus diseases noted the phenomenal advances and rapidly widening interest in these diseases.<sup>4</sup>

Before any vaccine can be used clinically it must run the usual gamut of experimental trial on human beings. Because of the importance of mumps in military medicine a considerable amount of investigative work was undertaken by members of the United States Public Health Service to work out a practical means of determining susceptibility and of prophylactic immunization. The editorial (J A M A, March 1947) led one to believe that the final product would be a viable vaccine. Should this product, of necessity be a viable virus, its use would be limited by the same factors which limit all viable products. Preparations of the live virus are wholly unsatisfactory since the patient can be given no assurance that he would not become ill with the disease against which immunization is desired.

In a report by Enders and associates in 1946, it was concluded that the mumps virus after twenty five passages in the chick embryo appeared to be incapable of inducing "typical mumps" in "presumptively susceptible" human beings, when sprayed into the oral cavity. They also found that this material might irregularly lead to the formation of a complement fixing antibody (here after designated as CFA).<sup>5</sup>

From the Department of Internal Medicine Indiana University Medical Center and The Lilly Research Laboratories

Received for publication Sept 15 1948

Habel has been able to produce parotitis in monkeys on immunization attempts with live egg embryo virus and therefore it seems unlikely that such a viable product would survive clinical criticism. Furthermore, Habel has stated (personal communication) that although he had not used a live virus preparation in human subjects, his virus strains were still able to produce a "good parotitis" in monkeys after thirty egg passages. He stated in unpublished data that he had "good results" with the inactivated virus given intramuscularly to human beings. He concluded from the latter data that there was no good reason for using the active virus.

We propose to present clinical data concerning the use of intracutaneous, nonviable mumps vaccine on a group of unselected human volunteers. The volunteers consisted of medical students, nurses, and patients at the Indiana University Medical Center and Indiana University School of Medicine.

*Mumps Virus Strains*—Two strains of mumps virus were used: one was procured from Dr. K. Habel,\* and the other from Dr. J. Enders†. In tests conducted by us, no differences have been found between the two strains.

*Cultivation of the Virus*—The virus was propagated by inoculating 7-day-old chick embryos which were incubated at 35° C. temperature. Inoculation of the eggs was similar to the usual technique for that of the influenza viruses. The periembryonic fluids were harvested. Tests showed them to contain the highest content of the virus.

*Properties and Control of the Virus*—Since mumps virus propagated by egg passage is not infectious for the smaller laboratory animals, the presence of virus in the egg fluid is determined by complement-fixation (Bengtson technique)<sup>6</sup> and hemagglutination tests (Hirst technique).<sup>7</sup>

Swiss mice were given periodic intranasal instillations of the virus to check chance contamination with other viruses, and homologous and heterologous inhibition of hemagglutination tests were done with mumps and influenza viruses and the corresponding antisera.

*Laboratory Test of Mumps Virus and Production of Mumps Antiviral Serum in Rats and Rabbits*—Each yield of vaccine was tested in five rats, the animals being injected intraperitoneally with 0.2 cc. on alternate days, then bled one week after the sixth and final dose of vaccine. With normal rat sera as a control, complement fixation and hemagglutination inhibition tests were conducted with these sera to determine the amount of response. Titers of rats immunized in this way are not unlike those of human beings. Antiviral serum was produced in rabbits by twice weekly intravenous injections of 5.0 cc. of the egg-passage antigen. The animals were bled one or two weeks after the eighth and final injection.

*Preparation of Skin Test Antigen*—The periembryonic fluid virus antigen was centrifuged for a short time to clarify it, then diluted to contain 20 complement-fixing antigen units per cubic centimeter. The antigen was then heated to 65° C. for ten minutes, tested for sterility, and Merthiolate (sodium ethyl

\*United States Public Health Service

†Children's Hospital, Boston, Mass.

mercuri thioacetate, Lilly) 1:10 000 was added as a preservative. The virus is susceptible to the inactivating effects of heat, formalin, ether and ultra violet irradiation.<sup>8</sup>

Our CF antigen, as present in this skin test antigen, is of course the "virus bound" antigen as described by Henle, Henle, and Harris.<sup>9</sup> It exists primarily in the perieμβryonic fluids as distinguished from the mumps embryo membrane antigen. According to Henle and co-workers the virus bound antigen is sedimentable at 20 000 revolutions per minute. The corresponding CF antibody, while slower in appearance persists longer after termination of the disease. On the other hand the "soluble" smaller size nonvirus CF antigen associated with fixed tissue (and with which we have not dealt) gives a short term antibody response in clinical mumps.

#### CLINICAL STUDIES

*Skin Tests*—One tenth cubic centimeter of vaccine containing 20 complement fixing units was placed intracutaneously on the flexor aspect of the forearm.

*Skin Test Reading*—Tests were read as positive if the area of erythema and induration (edema) was larger than 1 cm, negative if the zone of erythema was not greater than 2 cm and showed no evidence of induration. All skin tests were read between twenty four and thirty six hours at which time the local reaction was at its maximum.

The color which developed was similar to that seen with the routine Mantoux skin test with tuberculin.

SUGGESTED INTERPRETATION (ARBITRARILY SET AFTER OBSERVING 400 SKIN TESTS)				
1+	1 cm	→	2 cm	diameter
2+	2 cm	→	3 cm	diameter
3+	3 cm	→	4 cm	diameter
4+	4 cm	→	Greater	

*Skin Tests*—Four hundred intracutaneous injections each containing 20 units of complement fixing antibody have been given to date. There has been no evidence of systemic reaction or untoward symptoms. The typical local reaction in persons who had a definite history of mumps and a significant CFA titer was an erythematous indurated area of 2 by 3 cm to 3 by 6 cm. The epidermal tissue acquires hypersensitivity to the antigen following previous experience with the living or killed virus.

Originally the test was designed as a method for demonstration of an allergic response to the heat inactivated virus. It was supposedly a convenient index of determination of susceptibility or resistance of the individual to heat inactivated virus. Evidently from the clinical data furnished by Enders and co-workers in 1945, their inactivated virus produced little or no immunity as measured by the complement fixing procedure. Their antigen was prepared from the infected monkey parotid glands from infected eggs as described.<sup>10</sup>

Hypersensitive state (that is, positive skin test) could first be demonstrated between the second and third month following convalescence.<sup>10</sup> It was therefore

concluded that the skin test would have no value in diagnosis during the active disease. Presumptive diagnosis can be made from the clinical picture and an absolute diagnosis from rising C F A titers and culture of specific virus.

Enders stated that "this skin test material" was weakly antigenic, capable of stimulating the production of antibody in certain of those previously infected but incapable of inducing "de novo" antibody formation in those who have not encountered the virus. Attempts at local passive transfer by technique of Piantitz and Kustner could not be demonstrated.<sup>10</sup>

Fig 1

Human convalescent serum of high titer in C F A was injected into the skin of an individual who had previously failed to react to the skin test material. After an interval of twenty-four hours, 0.1 cc skin test material was injected into the same area. No immediate or delayed reactions were noted.<sup>10</sup>

Enders presented evidence that individuals who were exposed to the virus, yet showed no clinical evidence of the disease, developed a gradually rising C F A titer and rightly concluded that an inapparent infection had been present.

The intracutaneous skin test was applied to a group of volunteers four months after a previous test with the same material. In the majority of the cases there was a more marked reaction to the second dose. Readings which were originally 1+ and 2- were greater than the minimal 4+ (4 cm) reaction in many. A group of volunteers who had negative skin tests originally had 3 to 4+ on their second skin test. Work on C F A titration will be reported later. The opposite arm was used for subsequent skin tests to avoid possibility of local hypersensitivity.

From these results we are forced to question the significance of a second positive skin test in people who have the clinical picture of mumps. We do not believe that a second positive skin test would substantiate a clinical diagnosis.

since we have shown rises in CFA titers comparable to those in mumps following one skin test dose. A rising CFA titer would be very significant if not influenced by inactivated antigen via the intradermal or subcutaneous routes.

Comparative studies of history and intradermal sensitivity on information obtained from individuals having one skin test dose of antigen are seen in Fig 1

Fig 1

#### CF STUDIES

Enders (Harvard University) reported complement fixation tests for diagnosis of mumps made from egg antigen to replace the more expensive and less practical source from monkeys.

To show the rise in titer he stated that the test should be made with two specimens of serum, one taken soon after the onset of the disease the second at the end of the third week, for most of the convalescent serums showed a high titer after the second week.

In a series of seventy five unselected cases we gave 20 complement fixing units of heat killed mumps virus vaccine. Prior to intracutaneous injection of the nonviable mumps virus a specimen of blood was obtained to check the complement fixing antibody titer as a control.

Four weeks later a second specimen was collected and its complement fixing antibody titer was also determined. Fig 2 gives us a graphic representation of the CF antibody titrations before and after the intradermal dose of vaccine.

Enders and co-workers reported positive complement fixation tests on 1+ or 2+ reactions. Our figures are correspondingly much lower since a "positive" C F reaction was read as a positive to the first 2+ reaction, for example

Sample case	1 2	1 4	1 8	1 16	1 32	1 64	1 128	1 256	1 512
	4+	4+	4+	2+	2+	2+	1+	1+	1+
	1 16 was the end point								

It is evident that a marked change took place in the C F antibody titer (Fig 2)

Studies of specimens taken two weeks following intradermal vaccine showed significant rises in C F antibody titrations above the control serums checked (Results to be reported in a subsequent report)

This is comparable to studies done on convalescing mumps patients by the Harvard group. In four cases described by Enders and co-workers the C F antibody made its appearance before hypersensitivity could be demonstrated. In many cases C F A was present on the first day of clinical symptoms. Dermal hypersensitivity from mumps may last as many as fifty years. This was demonstrated in several elderly subjects.

Comparative studies between history, intradermal sensitivity and complement-fixing antibody titration are illustrated graphically in Fig 3.

#### DISCUSSION AND CONCLUSIONS

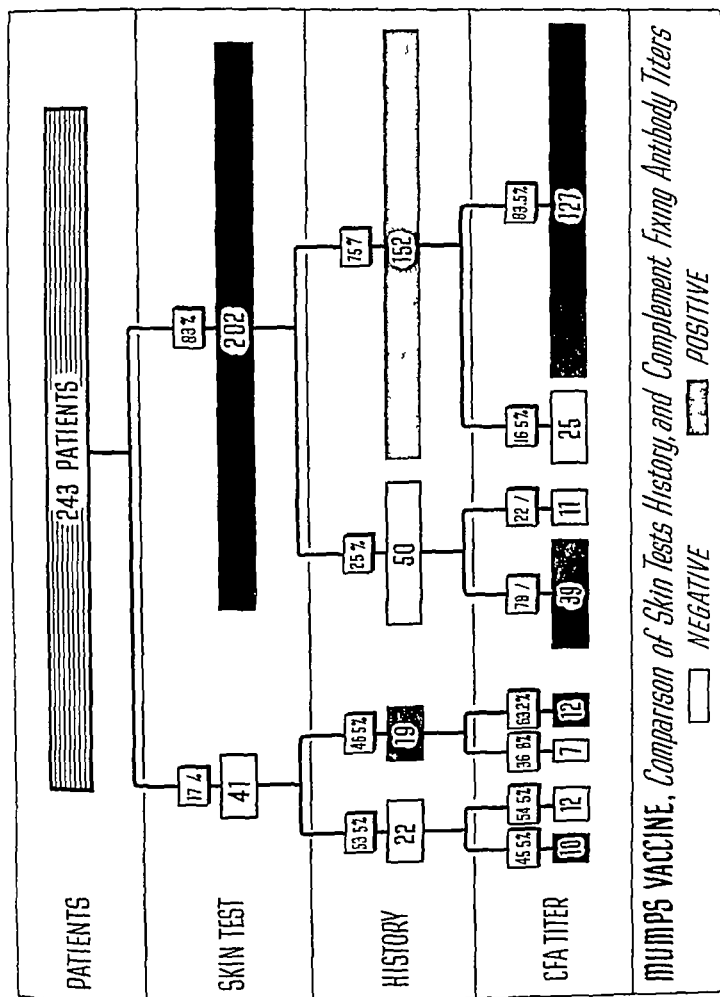

Mumps becomes an important disease whenever proximity of rural and urban people becomes a necessity, for example, military camps, summer camps, and university centers.

It has been reported by Fox that during World War I mumps was third among the diseases causing loss of duty time. Venereal disease and influenza were listed as first and second offenders. The Surgeon General of the United States Army reported that in 1918 mumps accounted for 7.15 per cent of admissions to army hospitals. A total of over 166,000 cases was reported. Wollstein reported epidemic parotitis as the fourth disease in the list of causes of admission to hospitals, but it was the second largest cause for loss of time. In 1940, Surgeon General Parran of the United States Public Health Service stated that mumps was second only to venereal diseases among the disabling acute infections of recruits.

It must be remembered that the incidence, high as it is, is actually relatively higher because most individuals have had the disease in childhood. Radin, in 5,756 cases, found forty-seven with a history of previous attack—0.8 per cent.<sup>11</sup>

In 1943, a "heavily infected" company of 194 soldiers at Camp McCoy, Wis. was studied. Nineteen per cent of the group contracted mumps during the sixteen weeks which elapsed between the onset of the first and last case. This percentage closely parallels our cases who had negative skin tests.

Thirty-two per cent of the soldiers at Camp Wheeler (World War I) had mumps at one time or another during their stay at camp. In the A E F during World War I, one in every twenty white men and one of every six Negroes had an attack.

The total mortality in the U S Army in World War I accredited to mumps as the original diagnosis was 181, but these deaths were associated in every case with a secondary diagnosis which requires consideration in at least partially acquitting mumps of responsibility <sup>12</sup>

Eagle reported a four-year mumps epidemic in one camp in which 2,500 patients were hospitalized. Of 1,664 cases reviewed, epididymo-orchitis occurred in 25.54 per cent <sup>13</sup> (The average age of patients was 24.79 years). In this age group it is a debilitating disease of no small consequence. McGuinness and Gall studied 1,331 cases at Camp McCoy and found 36.2 per cent of the patients with mumps with epididymo orchitis. Orchidotomies were performed on eighty-three soldiers at Camp McCoy <sup>14</sup>

Gregg in 1941 pointed out the high incidence of congenital malformation in children born to mothers who had German measles (rubella) during the early months of pregnancy <sup>15</sup>. Since then, the work has been confirmed by several other workers, more than 400 cases being reported. Incidence of malformations following rubella infection in the first two months of pregnancy is almost 100 per cent. Abnormalities resulting from rubella infection in the pregnant mother: cataract, heart defects, microcephaly and deaf-mutism.

This work stimulated further research to determine the effect of related viruses, for example influenza A and mumps. Hamburger and Habel <sup>16</sup> found that infection of 8-day-old chick embryos resulted in mumps virus multiplication in the allantoic sac, although the mumps virus was lethal for early embryos within five days after infection. They presented well controlled experimental evidence to show that mumps virus has questionable teratogenic effect on early chick embryos (studies have not yet been completed).

Johnson and Goodpasture attempted to confer passive immunity to intra-parotid infection by injection of serum from persons immune to mumps. These attempts failed except in rare cases <sup>17</sup>.

Pooled human serum has been used as a prophylactic measure in individuals exposed to mumps. There are several disadvantages to this method of prophylaxis.

- (1) The period of immunity is probably short.
- (2) Immune serum from convalescent patients should be taken within three weeks of onset date to be most efficient.
- (3) No. 2 makes large scale immunization impractical in epidemics.
- (4) The amount of pooled serum recommended varies between 20 and 40 cc in adults and in our experience has proved very painful to the recipient.
- (5) There is always a danger of transmitting homologous serum hepatitis <sup>18</sup>.

Several considerations present themselves.

- (1) What individuals should be vaccinated?
  - (a) Should the vaccine be used in children?
  - (b) Would the immunity conferred by the disease itself be more lasting than that given by the vaccine? (We are confronted with the problem of the age at which attempts at immunization should begin.)

- (2) Would the vaccine prevent early fetal death and congenital abnormalities due to mumps in infants if pregnant mothers were vaccinated in early pregnancy that is if they gave no history of having mumps in the past?
- (3) Does mumps produce a lasting immunity to all manifestations of the disease or merely prevent the recurrence of parotitis?
  - (a) If so should the vaccination be given in spite of a positive history?
  - (b) What place would the vaccine have in immunization of the military forces?
- (4) What place does the vaccine have in a mumps epidemic?
  - (a) Should all nonimmune people (from individual history) who contract cases be vaccinated?
  - (b) Would a vaccination protect them or does the rapid incubation period prohibit development of immunity in time to protect the individual?
- (5) Since immune globulin gives only short passive immunity should both immune globulin and the vaccine be given concomitantly?
- (6) Are "booster" doses necessary? If so when?

Obviously, studies in epidemiology cannot be carried out at a medical center for a scarcity of active cases exists. The ideal proving ground for such immunologic study will rest in large military camps where epidemics are common.

Ratner and Untriet in studies of egg vaccine and egg sensitivity concluded that the "Use of vaccines is not dangerous to 99.5 per cent of the general population, which included all the allergic persons who are sensitive to proteins other than egg and about 50 per cent of the persons moderately sensitive to egg."<sup>10</sup>

Demonstration of rising CFA constitutes a valuable clinical diagnostic aid. Central nervous system involvement during mumps had been studied extensively. A rising specific CFA titer for one of the virus infections may help categorize and prognosticate heretofore unclassified encephalitides. Brown and co-workers reported seventy-seven consecutive cases of mumps in which spinal fluid examination was made. Pleocytosis was present in twenty-six (33.7 per cent). Clinical manifestations of meningoencephalitis were recognized in nine cases.<sup>20</sup>

#### SUMMARY

1 Mumps vaccine prepared by inactivation of the living virus (by heat) has been given intracutaneously to a series of human volunteers.

2 Mumps virus strains were propagated on chick embryos. Vaccine was prepared from the heat killed virus.

3 Methods of preparation of the virus and immunization material are presented.

4 Two complement fixing units (0.1 cc of vaccine) were injected intradermally. Hypersensitive reactions seemed to indicate previous contact with the virus in the subclinical or clinical forms. In addition, the same hypersensitivity developed after the first intradermal dose.

5 The mumps vaccine given to our volunteers served as an index of potential susceptibility to mumps and positive reaction implied a previous clinical

or subclinical infection with the virus. The skin test dose caused significant rises in complement-fixing antibody titers and might possibly be a practical method of vaccination. Work is in progress to determine the optimal dose and route of administration.

6 The vaccine caused no untoward reaction in 400 human subjects.

We have no evidence that the immunity which our intradermal vaccine produces will be a permanent one. Follow-up studies of our volunteers will be necessary.

The potential value of the mumps vaccine has, in part, been determined. The actual value of mumps vaccine remains as an unsolved problem.

Long-term immunologic epidemiologic studies must be planned and will be necessary in order to arrive at the solution of the problems presented.

## SPONTANEOUS AND INDUCED GLOMERULONEPHRITIS IN AN INBRED STRAIN OF MICE

ARTHUR KIRSCHBAUM M.D. PH.D. I. T. BEIL M.D. AND JACK GORDON M.D.  
MINNEAPOLIS, MINN.

A SPONTANEOUS disease simulating chronic glomerulonephritis has not been recognized in animals except in the NH strain of mice<sup>1</sup> with which this report deals. This stock of animals is of special significance because it represents a population in which the incidence of the disease is high. It should be possible therefore to study etiologic factors under controlled conditions.

The NH stock was developed by Dr. L. C. Strong, of the Yale University School of Medicine. In the fourth inbred generation four sublines were separated. One of these was established in Minnesota in the eighth inbred generation in 1941. Although the present stock of the Minnesota subline is represented by descendants of a pair of mice brought to Minnesota at that time, brother-sister mating was not carried out until 1943 when it was recognized that the animals develop glomerulonephritis. Subsequently selection of mice possessing genetic susceptibility toward the disease has been attempted by mating the progeny of animals which develop nephritis.

The NH mice are very obese animals at the age of six months. Old adults may attain a weight of 50 grams which is almost twice that of the average inbred mouse. Subcutaneously and intra-abdominally there are very large deposits of fat. The females especially, but males as well, develop tumors of the adrenal cortex when the animals are over 1 year of age. Leucemia appears spontaneously in about 5 per cent of the mice, also occasional lung tumors. The males develop a distention of the bladder spontaneously at about 1 year of age in association with which hydronephrosis appears. The average life expectancy has been approximately 600 days.

Initially the animals were maintained in the laboratory for no particular purpose except to provide mice for routine experiments that necessitated no special type of genetic susceptibility. It was noted that many NH females which died between the ages of 11 and 20 months were extremely edematous at autopsy. There was often in excess of 1 cc of clear fluid in the chest and more than 2 cc in the peritoneal cavity. The subcutaneous edema was so extreme that the distance between the abdominal muscles and epidermis was expanded to a half inch. This fluid was usually serous and colorless although subcutaneously it was often yellow tinged. Animals which developed ascites, hydrothorax, and mastitis usually died within a week. In certain instances this edematous condition subsided temporarily but there was always recurrence with death in every case. No animal survived more than three weeks after the

## SPONTANEOUS AND INDUCED GLOMERULONEPHRITIS IN AN INBRED STRAIN OF MICE

ARTHUR KIRSCHBAUM, M.D., PH.D., L. F. BRETHERTON, M.D., AND JACK COLEMAN, M.D.  
MINNEAPOLIS, MINN.

A SPONTANEOUS disease simulating chronic glomerulonephritis has not been recognized in animals except in the NIH strain of mice<sup>1</sup> with which this report deals. This stock of animals is of special significance because it represents a population in which the incidence of the disease is high. It should be possible therefore to study etiologic factors under controlled conditions.

The NIH stock was developed by Dr. L. C. Strong, of the Yale University School of Medicine. In the fourth inbred generation four sublines were separated. One of these was established in Minnesota in the eighth inbred generation in 1941. Although the present stock of the Minnesota subline is represented by descendants of a pair of mice brought to Minnesota at that time, brother-sister mating was not carried out until 1943, when it was recognized that the animals develop glomerulonephritis. Subsequently selection of mice possessing genetic susceptibility toward the disease has been attempted by mating the progeny of animals which develop nephritis.

The NIH mice are very obese animals at the age of six months. Old adults may attain a weight of 50 grams, which is almost twice that of the average inbred mouse. Subcutaneously and intra-abdominally there are very large deposits of fat. The females especially, but males as well, develop tumors of the adrenal cortex when the animals are over 1 year of age. Leucemia appears spontaneously in about 5 per cent of the mice, also occasional lung tumors. The males develop a distention of the bladder spontaneously at about 1 year of age in association with which hydronephrosis appears. The average life expectancy has been approximately 600 days.

Initially the animals were maintained in the laboratory for no particular purpose except to provide mice for routine experiments that necessitated no special type of genetic susceptibility. It was noted that many NIH females which died between the ages of 11 and 20 months were extremely edematous. At autopsy there was often in excess of 1 cc of clear fluid in the chest and more than 2 cc in the peritoneal cavity. The subcutaneous edema was so extreme that the distance between the abdominal muscles and epidermis was extended to a half inch. This fluid was usually serous and colorless although subcutaneously it was often yellow-tinged. Animals which developed ascites, hydrothorax, and anasarca usually died within a week. In certain instances this edematous condition subsided temporarily but there was always recurrence with death in every case. No animal survived more than three weeks after the

Received for publication Sept. 20, 1948.

onset of the clinical disease. There appeared to be no antecedent occurrence of disease, renal or otherwise. Animals which apparently had been in good health suddenly became quite edematous and died. The disease has occurred exclusively in females.

Grossly the kidneys were of normal size, but always pale. Examination of the kidneys microscopically revealed that the seat of the pathologic disturbance was in the glomerulus. The glomeruli exhibited changes which correspond closely to those of human chronic glomerulonephritis, and the tubules contained protein casts. Microscopically the condition is quite different from the amyloid (cystic) disease which occurs in other stocks of mice, especially the Strong A<sup>3</sup>. A glomerular lesion similar to that found in the NH mice also has been seen by the authors in two mice of the F strain (Fig. 6, 13 and 14).

The following discussion presents observations on the spontaneous disease in this stock of animals, and a similar condition induced by the administration of urethane.

#### MATERIALS AND METHODS

A control group of NH mice was maintained to determine the incidence of spontaneous chronic glomerulonephritis. All animals were bred and fed a diet of Purina Fox Chow with no supplement. Water was always available. Often the disease was diagnosed subsequent to the death of the animal since the mice died very soon after the clinical onset of the disease. Complete autopsies were done, sections being cut at 5 micra and stained with hematoxylin and eosin. In addition all kidneys were stained with azocarmine after fixation in Zenker's fluid. Certain kidneys were fixed in formalin and stained for amyloid.

After the onset of edema the mice were placed in specially constructed glass cages for collection of urine. Albuminuria was ascertained by the routine method of boiling and acidification. For blood determinations blood was drawn immediately after the animals had been killed with ether anesthesia. Blood was taken from the vena cava and oxalated. Plasma and blood obtained in this way were used for determining blood urea nitrogen, nonprotein nitrogen, plasma proteins, hemoglobin, red blood cell counts, and the titer of antibodies against streptococci. The Karr method<sup>4</sup> was used for the determination of blood urea nitrogen, the method of Koch and McMeekin<sup>5</sup> for nonprotein nitrogen and plasma protein and Bloor's method<sup>6</sup> for cholesterol.

Agglutinin titers were determined against strains of *Streptococcus viridans* and *Streptococcus hemolyticus* obtained from human sources. Twenty-four hour broth cultures were used.

Pure cultures of *Str. viridans* were obtained from the pharynges of both normal and nephritic strain NH mice. These organisms were autoagglutinating and could not be used for agglutination tests. However, when injected intraperitoneally into mice, the antiserum thus produced contained antibodies active against the streptococci from the human source. This procedure was carried out to demonstrate the common antigenic properties of streptococci from mouse and human sources, and thus justify the use for agglutination studies of the *Str. viridans* and *Str. hemolyticus* of the human pharynx.

To determine whether the plasma of nephritic mice was nephrotoxic and contained antibodies specific for mouse renal antigen, the plasma was tested using the method of Cavelti and Cavelti<sup>7</sup> for the preparation of the renal antigen. Perfused kidneys of both normal and nephritic mice were used as the source of antigen. One part perfused kidney to 20 parts saline was used in making the test antigen for determining agglutination titers. Control studies were carried out on nephrotoxic rabbit plasma obtained from rabbits injected periodically with a saline extract of perfused mouse kidney.

## INCIDENCE OF URETHANE INDUCED GLOMERULONEPHRITIS

Fig 4—Illustrates the age of occurrence and incidence of urethane-induced glomerulonephritis in NH mice of both sexes

The age incidence of spontaneous nephritis in female NH mice is presented in Fig 1. Seventeen out of forty-eight females developed the disease, which appeared between the ages of 11 and 19 months. By contrast, none of twenty-eight males, all of which lived eleven or more months, developed nephritis (Fig 2). Four of forty-seven castrated males developed the disease (Fig 3). These observations were on pedigreed stock. Previous to inbreeding, twenty-four cases had been observed in a group of fifty-nine females, and one questionable case in seventy-one males.

All female mice 11 months or more of age had estrogen-secreting adenomas of the adrenal cortex, whereas such adenomas did not appear spontaneously in males. When either males or females of this stock are castrated, these adenomas are present within five months. Thus, all the castrated males possessed cortical adenomas which secreted estrogenic hormone<sup>10</sup>.

Although the disease did not appear spontaneously in males, animals of both sexes injected with urethane in the manner described developed clinical nephritis (Fig 4) which was grossly indistinguishable from the spontaneous disease. Neither Bagg albino, CBA, Strong A, nor FA mice responded in a similar manner. Thus, in only mice of the "high nephritis" NH stock was glomerulonephritis induced by urethane.

Fig 5—5. Renal corpuscle of adult male NH mouse. Parietal layer of Bowman's capsule composed of cuboidal epithelial cells indicating androgenic stimulation. Capillary loops of glomerulus well shown. Delafield's hematoxylin-basic fuchsin. Photomicrograph X350.

6. Renal cortex from a spontaneous case of chronic glomerulonephritis in an NH female mouse. The glomerular capillaries are almost completely occluded and some hyaline changes are noted. Azocarmine stain. Photomicrograph X200.

7. Glomerulus from a spontaneous case of chronic glomerulonephritis in an NH female mouse. The glomerular capillaries are completely occluded by endothelial cells. This lesion corresponds closely to human acute glomerulonephritis. Azocarmine stain. Photomicrograph X275.

8. Glomerulus from spontaneous chronic glomerulonephritis in an NH female mouse. The central capillary basement membranes have thickened and fused to form hyaline masses in the centers of the lobules. Many of the capillaries in the periphery of the lobules are still open. This closely resembles the early chronic stage of human glomerulonephritis. Azocarmine stain. Photomicrograph X350.

9. Kidney section from spontaneous chronic glomerulonephritis in an NH female mouse showing casts in the tubules. Azocarmine stain. Photomicrograph X150.

10. Amyloid deposits in the renal corpuscles of an NH female mouse following long term administration of urea. Note that this lesion is entirely different from glomerulonephritis. Hematoxylin-eosin. Photomicrograph X150.

Fig 5—(Legend on opposite page )

In urethane-treated mice the glomerular lesions were not identical with those seen spontaneously (Fig 6, 11, and 12). In the latter the endothelial proliferation is the most prominent pathologic feature. In urethane-induced nephritis, thickening of the capillary basement membrane is much more conspicuous than endothelial proliferation (Fig 6, 11). The end result is a fibrotic glomerulus (Fig 6, 12) which is smaller than the hyaline glomerulus of the spontaneous case (compare Fig 5, 8 and Fig 6, 12). The development of this type of glomerulus is determined not only by urethane but also the genetic constitution of the host. Although the glomeruli of neither Bagg albino nor CBA mice became fibrous as a result of the administration of urethane, many of the hybrids (receiving urethane) between either of these stocks and NH mice developed the small hyaline glomeruli. The tendency toward *clinical* nephritis is not as great in hybrids as in pure NH mice.

Lesions other than those in the kidneys were noted in mice injected with urethane. Adenomas of the lung<sup>11</sup> appeared in all stocks of mice thus treated. Cavernous hemangiomas were present in the livers of certain animals receiving urethane, especially mice of the Bagg albino strain and hybrids between this and other strains.

#### DISCUSSION

The glomerular alterations occurring spontaneously in female NH mice seem to be identical with those of human chronic glomerulonephritis.<sup>12</sup> Secondary tubular atrophy is not prominent, however, in the mouse kidneys. Perhaps an insufficient period of time elapses in the mouse between glomerular closure and death so that tubular atrophy may result. Glomerular lesions were widespread (Fig 5, 6) and glomerular closure seemed to be rather complete in some cases.

Determination of antibodies failed to reveal any information indicating an association of infection with the mouse disease. Some of the glomeruli exhibited endothelial proliferation (Fig 5, 7) as in human acute glomerulonephritis associated with bacterial infection. It is possible that the human and mouse diseases are pathologically and clinically similar, but etiologically unrelated. Or perhaps chronic glomerulonephritis is not necessarily associated with antecedent bacterial (streptococcal) infection.\* High antistreptolysin titers have been found in human acute but not chronic glomerulonephritis.<sup>13</sup>

Mouse and rat glomeruli exhibit a sexual dimorphism<sup>14</sup> (Fig 5, 5), and there is a sex difference in the occurrence of this renal glomerular disease. That this susceptibility to the development of glomerulonephritis is, at least to some extent, on a hormonal and not only a genetic basis is illustrated by the occurrence of the disease in castrated males with estrogen-secreting adenomas of the adrenal cortex. The incidence of the disease in castrates is admittedly small. The possible inhibiting effect of androgen on the development of spontaneous and induced nephritis should be tested.

\*Dr. B. J. Clawson of the Department of Pathology, University of Minnesota, has informed us that he has found high titers of streptococcal (*Str. viridans* and *Str. hemolyticus*) agglutinins in several cases of human chronic glomerulonephritis.

Fig 6—11 Thickening of glomerular capillary basement membrane in urethane treated NH mouse. This lesion bears some resemblance to human lipoid nephrosis. Azocarmine stain. Photomicrograph X350.

12. Small fibrotic glomerulus resulting from urethane treatment. The capillary lumens are occluded by the thickened basement membranes. Such glomeruli were found only in urethane treated mice of the NH strain. Azocarmine stain. Photomicrograph X300.

13. Glomerulus from a strain F mouse with chronic glomerulonephritis. The disease occurs occasionally in this strain and the lesions are similar to those found in NH mice. Azocarmine stain. Photomicrograph X300.

14. Glomerulus from a strain F mouse showing one portion with capillaries plugged as a result of endothelial proliferation. Note mitotic figure. Hematoxylin eosin. Photomicrograph X350.

Blood studies indicate a high degree of renal insufficiency and anemia in the advanced disease. These animals represent good material for the investigation of the anemia associated with uremia. Hypercholesterolemia is, perhaps, to be related to the low level of plasma proteins.

The concomitant occurrence of spontaneous tumors of the adrenal cortex and renal disease in females of this stock may be merely coincidental. Animals injected with urethane developed glomerulonephritis in the absence of adrenal cortical hyperplasia. There is no evidence that these adenomas may secrete hormones other than the sex steroids.

Since other investigators have been able to induce glomerulonephritis in rats by the injection of nephrotoxic sera,<sup>15</sup> determination of antibodies versus renal antigen was made. There was nothing to indicate that specific antibodies against a renal antigen were present in the plasma of nephritic mice (Table VI).

TABLE VI AGGLUTINATION TITERS AGAINST NORMAL AND NEPHRITIC RENAL ANTIGEN IN THE PLASMA OF NORMAL AND NEPHRITIC MICE

TOTAL NUMBER OF MICE	TREATMENT	AGGLUTINATION TITER VS		NUMBER OF MICE
		NORMAL KIDNEY	NEPHRITIC KIDNEY	
7 Nephritic (spontaneous)	None	Neg 1 50 1 100 1 200		4 1 1 1
2 Nephritic (spontaneous)	None		Neg 1 100	1 1
8 Normal	None	Neg 1 50 1 100		6 1 1
2 Normal	None		Neg	2
4 Normal	Kidney inject	Neg 1 200		2 2
5 Normal	Kidney strep inject	Neg 1 100 1 200		2 1 2
4 Normal	Liver strep inject	Neg 1 400		3 1

0.1 cc nephritic rabbit sera (antimouse kidney) with titers of 1 800 or more induced passive agglutination in mice. The values obtained in this table may represent nonspecific agglutination.

The influence of streptococcal infection and streptococcal toxins on the development of renal glomerular lesions in NH mice should be determined. Preliminary experiments indicate that inoculations of *St. viridans* over a period of several months do not cause nephritis to appear precociously in NH mice. It should also be determined whether substances related to urethane (ethyl carbamate) affect the renal glomeruli. Nephritis was not induced by injections of either urea or thiourea although amyloid disease appeared in some animals so treated (Fig 5, 10). Weekly anesthetic doses of Sodium Amytal or magnesium sulfate also failed to induce renal disease in NH mice. Thus, anesthesia per se (urethane is a general anesthetic) would appear not to be a factor of importance in the response of NH mice to urethane.

The genetic aspects of NH nephritis have not been investigated although the disease has been observed by the authors in F<sub>1</sub> hybrids between the NH and

other strains of mice. This is in contrast to the amyloid cystic disease of strain A mice, susceptibility to which is inherited as a Mendelian recessive.<sup>16, 17</sup> Amyloid cystic disease also appears in mice of both sexes. Histologic studies show clearly that the occlusion of the NII glomeruli is not the result of deposition of amyloid. Spontaneous amyloid disease does occur occasionally, however, in mice of the NII stock.

The tendency to develop fibrotic glomeruli following the administration of urethane is also not heritable as a simple Mendelian recessive. All types of hybrids ( $F_1$ ,  $F_2$  and back crosses) developed urethane glomeruli following twenty weekly doses, although clinical nephritis appeared only occasionally in hybrids. It is unlikely that the susceptibility of NII mice to both spontaneous and urethane-induced nephritis is without causal relation. Although histopathologically the spontaneous and urethane-induced diseases are not identical, in both instances there is occlusion of the glomerular capillaries and the renal lesions are confined to the glomeruli.

Preliminary observations suggest a rise in blood pressure in mice with glomerulonephritis; this subject will be considered in a future communication. Histologically the amount of renal glomerular closure may be extreme. However, the small amount of tubular degeneration suggests that renal ischemia is not general. Perhaps the renal tubules of mice are supplied from an arterial source other than the efferent arterioles.

#### SUMMARY

1. A disease resembling human chronic glomerulonephritis occurs spontaneously in female mice of the NII stock. This disease is characterized by albuminuria, edema, nitrogen retention, hypoproteinemia, anemia, and hypercholesterolemia. The glomerular lesions are histologically identical with those of human chronic glomerulonephritis, but tubular atrophy is inconspicuous and the kidneys do not become contracted. Blood pressure is perhaps moderately elevated.

2. The disease appears in about 40 per cent of intact females and 10 per cent of castrated males; nephritis does not occur spontaneously in males. The age of occurrence is from 11 to 20 months.

3. The titer of antibodies specific for streptococci in the blood of nephritic mice is the same as in nonnephritic mice of the NII and other strains.

4. A disease similar to but not pathologically identical with the spontaneous nephritis was induced in strain NII mice of both sexes by the administration of urethane. Four other inbred stocks resisted the induction of glomerulonephritis by this drug.

# STREPTOCOCCUS VIRIDANS ENDARTERITIS OF AN ARTERIOVENOUS ANEURYSM

CURED BY PENICILLIN AND SURGICAL EXCISION

MORRIS STATT, M.D., AND T. G. ORR, M.D.  
KANSAS CITY, KAN.

MASSIVE doses of penicillin with the aid of secretory blocking agents such as Citronamide, have brought the formerly fatal subacute bacterial endocarditis within range of therapeutic control. However, even after cure of the infective agent, cardiac limitation due to valvular pathology remains and the danger of recurrence of the same illness is always present. This is also true in instances of bacterial endocarditis with the vegetations occurring on congenital cardiac anomalies. In subacute bacterial endarteritis in which the infected vegetations occur on arteriovenous communications outside the heart, it is possible to effect a permanent cure with penicillin and surgical removal of the aneurysm. Such arteriovenous communications may be congenital as in patent ductus arteriosus or may be the result of trauma as in arteriovenous aneurysms.

A few cases of bacteremia associated with arteriovenous aneurysms have been reported.<sup>1</sup> The first cure of bacterial endarteritis in such an aneurysm was recorded by Hamman and Richhoff<sup>2</sup> in 1935. In this case the arteriovenous aneurysm of the external iliac artery and vein resulted from a gunshot wound inflicted nine years previously. Surgical removal of the aneurysm was the only treatment in this case. In 1939 Leaman<sup>3</sup> reported the case of an arteriovenous aneurysm in a patient with bacteremia. Following surgical removal of the aneurysm the patient continued to have fever and apparently still had bacterial endocarditis. In 1942 Touroff, Lande and Kroop<sup>4</sup> reported a surgical cure of an infected arteriovenous aneurysm with resultant clearing of septicemia. The next recorded cure was by Lipton and Miller<sup>5</sup> in 1944. Septicemia associated with an arteriovenous aneurysm of the femoral vessels was cured by excision of the aneurysm. In 1946 Shumacker, Welford and Carter<sup>7</sup> reported the case of a 26 year old soldier who developed bacterial endarteritis in an arteriovenous aneurysm caused by a grenade wound two years before development of septicemia. This patient was treated with penicillin in doses of 100,000 to 200,000 units daily, with subsequent negative blood cultures. Surgical removal of the aneurysm effected a cure although viable organisms were present in the vegetations at the time of operation.

The case of bacterial endarteritis in an arteriovenous aneurysm described in this report was cured by removal of the aneurysm. The patient was first treated intensively with penicillin which resulted in sterilization of the blood stream before operation.

From the Departments of Internal Medicine and Surgery, University of Kansas School of Medicine.

Received for publication Sept. 27, 1948.

CASE REPORT—H H, an 18 year old white man, was admitted to the University of Kansas Medical Center on Jan 6, 1948. His chief complaints were fatigue, shortness of breath, palpitation of the heart, fever, and profuse sweats. There was no history of past disease which might have contributed to his present illness.

On Aug 2, 1944, this patient received an accidental gunshot wound of the right thigh while hunting. The femoral artery and vein were severed about 6 cm below the inguinal ligament. This resulted in gangrene of the foot and an amputation was done at the juncture

Fig 1—Roentgen ray picture of the heart before operation

of the middle and upper thirds of the right leg. Recovery was prompt and an artificial limb was fitted within six months after the amputation. Several months after the accident the patient noticed that he had a throbbing area in the upper right thigh, but since it did not cause pain or inconvenience he was not concerned about it.

He gave a history of frequent toothache, sore throat, and upper respiratory tract infections during the past two or three years. Eighteen months prior to admission to the hospital he began to have shortness of breath on exertion, weakness and fatigue, associated with "pounding" of the heart. These symptoms grew progressively worse until six months before entering the hospital, when the patient developed chills, fever, nausea, and vomiting. He also had frequent throbbing frontal headaches. He was treated by local physicians who noted that he had an enlarged heart, cardiac murmur, daily fever, and anemia. One of his physicians made a blood culture which was reported to contain an abundant growth of long chain streptococcus, and a diagnosis of endocarditis was made.

When this patient entered the hospital he was poorly nourished and obviously acutely ill. His temperature was  $100.2^{\circ}$ . The pulse was regular and of the water hammer type. De Musset's sign was present. The blood pressure in the right arm was 130/30 and in the left

Fig 2—Photograph of excised aneurysm (Pointer indicates vegetation)

arm 130/20. The entire precordium throbbed and pulsated, and the heart was enlarged as determined by percussion. There was a loud rasping systolic murmur and a soft diastolic murmur heard in the mitral area. Harsh systolic murmurs were heard to the left of the sternum in the second and third interspaces over the aortic area and over the carotid vessels. All peripheral vessels were throbbing, and showed the typical Corrigan type of pulse. The spleen was enlarged. An ovoid mass 4 by 6 cm in size was palpated in the right thigh just below the inguinal ligament. This mass was pulsating and expansile and a to and fro machinery type murmur was heard over the mass. The murmur was transmitted to the right lower quadrant of the abdomen and along the thigh to the knee. When the pulsation was obliterated by pressure over the femoral vessels, the pulse rate was reduced from 100 to 70. No temperature changes were noted in the right lower extremity. The leg had been amputated below the knee.

Examination of the urine showed a faint trace of albumin. The hemoglobin was 8.4 Gm and the white cell count was normal. The Wassermann and Kahn tests were normal. The total proteins were 6.04 Gm with normal albumin globulin ratio. The blood sedimentation showed a fall of 32 mm. at the end of an hour. Blood cultures on the second and third days after admission showed growths of *Streptococcus mitis*. With sensitivity tests to penicillin and sulfadiazine, the growth was inhibited by 0.48 unit per cubic centimeter and 25 mg per cubic centimeter respectively.

By x-ray examination the heart was enlarged, measuring 18 cm in its greatest diameter (Fig 1). One half of the inside diameter of the chest measured 15 centimeters. Electrocardiogram readings were: heart rate 88, P-R interval 0.16, rhythm sinus, QRS complexes upright in the limb leads, small S2, T waves upright in all leads, sound tracings of the heart showed diastolic and systolic murmurs at the apex associated with an increased first sound and evidence of a systolic murmur in the pulmonic area.

On the sixth day after admission to the hospital, penicillin in 300,000 unit doses was started and continued every three hours by intramuscular injections. Cironamide was also given in 2 Gm doses every three hours. Within twenty-four hours the temperature was normal and remained normal thereafter. Penicillin levels varied between 8.170 and 17.306 units per cubic centimeter. After three days of penicillin therapy the blood culture was negative and remained negative. Two transfusions were given which increased the hemoglobin to 11.7 grams. Although palpitation and fatigue continued, the patient was otherwise symptom free and had gained weight during thirty days of treatment. He received a total of 72,000,000 units of penicillin over a period of thirty days. The sedimentation rate showed very little change.

Forty-five days after admission to the hospital and thirty-nine days after the beginning of penicillin treatment, the arteriovenous aneurysm was completely excised. During the operation, as soon as the vessels leading to and from the aneurysm were clamped or ligated the pulse quickly dropped from 105 to 70 and the blood pressure increased from 130/30 to 140/90. One hour after operation a reduction in size of the heart could be detected by physical examination, as verified by several of the staff. There was a faint presystolic murmur in the mitral area but no systolic murmur was heard. No thrills were detected. Faint systolic murmurs were heard in the tricuspid, aortic and pulmonary valvular areas. On the day after operation the heart appeared to be relatively normal in size, the heart sounds were of good quality, and no thrills or murmurs were detected. The blood pressure averaged 140 systolic and 70 to 90 diastolic.

The excised aneurysm measured approximately 5.5 by 4 by 3 cm (Fig 2). The cavity of the aneurysm had numerous sacculations. Several pinkish and grayish white papillary projections were formed outside the sac. The pathologist reported a diagnosis of aneurysm with arteriosclerosis, calcification, ulceration, and acute and chronic inflammatory reaction with vegetations. Shadowy granular forms were found in the vegetations which suggested chains of bacteria.

The postoperative course was uneventful. The wound healed per primam. Repeated blood cultures were negative. The blood count and sedimentation rate returned to normal. Three days after operation the transverse diameter of the heart measured on the x-ray film was 16.5 cm, and ten days postoperatively the heart measured 14.8 cm in diameter (Fig 3). The heart appeared to be normal in size. The electrocardiogram was normal. No heart murmurs were detected with repeated sound tracings.

When dismissed from the hospital on March 11, 1948, approximately two months after admission, the patient apparently had recovered completely.

#### DISCUSSION

This 18-year-old patient on physical examination presented findings which were indicative of endocardial disease of the valves of the heart. In addition to marked enlargement of all chambers of the heart, he showed harsh murmurs

over the precordium, both systolic and diastolic in time. He gave, however, no history of previous cardiac difficulties, no evidence of congenital heart lesions early in life, nor did he present any findings of peripheral embolic phenomena. That no valvular lesions existed was proved by the rapid return of his heart to normal size in ten days and the subsidence of all murmurs within twenty-four hours following operation.

Fig. 3.—Schematic drawing of excised aneurysm.

It is a well known fact that transient streptococcus bacteremia occurs frequently in respiratory infections, sinus infections and in dental extractions. As in the case with damaged valvular endocardium, the damaged endothelium of an arteriovenous aneurysm will serve as a focus upon which bacteremia may settle and multiply. The infected aneurysm will then serve as a constant source of bacteremia. This patient was started on large doses of penicillin before sensitivity tests of his organism had been carried out and it

Fig 4—Roentgen ray film of the heart four days after operation

Fig 5—Roentgen ray film of the heart ten days after operation

was not deemed wise to reduce the dosage when once started. Vesell and Kross<sup>8</sup> recommend that bacterial endarteritis engrafted upon a patent ductus arteriosus should be treated vigorously with penicillin before operation. Should small emboli be dislodged during the trauma of surgery, morbidity is certainly reduced by earlier sterilization of vegetations. That this patient's vegetations were sterile was verified by culture and by microscopic study which revealed only shadowy forms of pre-existent organisms.

The fact that no vascular insufficiency evidenced by edema or temperature changes developed in the extremity following operation is not surprising since Pratt<sup>9</sup> reports that three to six months is sufficient time for completely adequate collateral circulation to develop in the presence of an arteriovenous aneurysm.

The recognition of endarteritis in arteriovenous aneurysms is particularly important at this time since an increase in frequency of such infections may be anticipated in the future as a result of wounds of blood vessels during the last war. Certainly it is of importance to bear in mind such a possibility in all cases of streptococcus septicemia since a dramatic and permanent cure can be effected in such cases.

#### SUMMARY

A fifth case of streptococcus septicemia due to endarteritis of an arteriovenous aneurysm is presented. A cure was achieved by the use of penicillin and surgical removal of the aneurysmal sac.

# THE RESISTANCE OF RECENTLY HEALED EXCISIONAL ULCER OF THE STOMACH TO HISTAMINE-INDUCED ULCER

E H HALE, M S, M D, AND M I GROSSMAN, M D, PH D  
CHICAGO, ILL

## INTRODUCTION

IT HAS long been known and repeatedly confirmed that a surgically produced defect in the gastric mucosa will heal spontaneously within three weeks, even in the presence of normal gastric secretion of acid and pepsin. Dragstedt<sup>1</sup> made acute ulcers from 1.0 to 1.5 cm in diameter in the mucosa of a Pavlov pouch, healing occurred in five to fifteen days. Matthews and Dragstedt<sup>2</sup> found that ulcers made in the pyloric mucosa of dogs with silver nitrate healed in fifteen to eighteen days. Morison<sup>3</sup> observed in the dog that defects 2 cm in diameter in the fundic and pyloric mucosa healed in two weeks. McIlroy<sup>4</sup> found that ulcers of the stomach, produced by burning with a hot wire, would heal in fourteen days in the fundus and seventeen days in the pylorus. Bolton<sup>5</sup> observed that experimental ulcers healed within three weeks regardless of their location in the stomach.

It also has been demonstrated that an excisional ulcer of the stomach will be delayed or prevented from healing if histamine in sufficient dosage is given within one to two days postoperatively. McIlroy<sup>4</sup> produced acute ulcers in the pylorus of seven cats and injected 10 to 20 mg of histamine acid phosphate subcutaneously on alternate days. In eight control cats the pyloric lesion required seventeen days to heal. In the cats given histamine, the initial lesion, instead of healing in from eight to fifteen days, had extended in six of the seven animals and perforated in one. Flood and Howes,<sup>6</sup> using cats and dogs, interpreted their observations as indicating that the injection of 1 to 2 mg of histamine per kilogram body weight twice daily interfered with the healing of prepyloric mucosal defects but not consistently with defects in the mucosa of the cardia. Similar results were reported by O'Shaughnessy<sup>7</sup> and Carnot and co-workers.<sup>8</sup> Price<sup>9</sup> has recently shown that the daily administration of histamine in beeswax to dogs causes extension of surgical excision ulcers in the stomach. The apparently negative results obtained by Friedenwald, Feldman, and Morrison<sup>10</sup> may be attributed to the low dose of histamine that was used (average daily dose of 0.8 to 1.2 mg given in one to three doses subcutaneously).

Hay, Vaico, Code, and Wangenstein<sup>11</sup> have shown that superficial and perforating ulcers of the pylorus and duodenum could be produced in dogs by the daily administration of 30 mg of histamine (base) in mineral oil and beeswax medium.

It was considered of interest to study the sensitivity of the healed excisional ulcer to histamine-induced ulcer.

## METHODS

Thirty three mongrel dogs ranging in body weight from 7 to 15 kg, were used. Surgical excisional ulcers were made on the lesser curvature of either the fundic or pyloric portion of the gastric mucosa. The pyloric defects were made 2 to 4 cm from the pyloric sphincter. Under ether anesthesia an appropriate longitudinal incision was made in the anterior wall of the stomach and the mucosa of the lesser curvature was evaginated through the wound. Approximately 1 sq cm of gastric mucosa was excised from the submucosa with scissors. After closure of the stomach and abdomen the dogs were allowed water on the first day and water and standard dog ration thereafter.

The histamine beeswax suspension that was used was prepared from the following formula: Histamine dihydrochloride (Imido Hoffmann La Roche) 60 Gm, peanut oil 30.5 cc and white beeswax 3.8 grams. The weighed amount of histamine was ground to a fine powder with a mortar and pestle. Four fifths of the total volume of peanut oil was then gradually mixed in and heated in an oven to 60°C. The beeswax and the remainder of the oil were melted together and added to the histamine mixture. After thorough mixing the suspension was aspirated into heated syringes. Thus the final volume of 36 cc was calculated to contain 100 mg of histamine base per cc of suspension.

The usual dose of histamine beeswax suspension was 30 mg of histamine base per dog given once daily intramuscularly. This is the dosage used by Hay and associates<sup>11</sup>. However, as the incidence of ulcer was rather low in the earlier experiments this dosage was increased two to eight times and given in two daily injections in many instances. Dogs FF through II were deprived of food and water on alternate days to enhance the ulcerogenic effect of histamine.

Three series of studies were performed:

- 1 Control experiments with histamine alone
- 2 Histamine injections begun three weeks after fundic excisional ulcer
- 3 Histamine injections begun three weeks after pyloric excisional ulcer

## RESULTS

*Control Experiments With Histamine Alone*—(See Table I) It may be noted that five out of twelve dogs had pyloric or duodenal ulcers. These ulcers varied in character from multiple acute hemorrhagic ulcers to single chronic, perforating ulcers. Weight loss occurred in all animals in which death was spontaneous. Anorexia and/or vomiting preceded death by one to three days in most cases.

TABLE I INCIDENCE OF ULCERS IN NORMAL DOGS RECEIVING HISTAMINE IN BEESWAX

DOG	SURVIVAL TIME (DAYS)	POST MORTEM FINDINGS		
		FUNDUS	PYLORUS	DUODENUM
JJ	4	Neg	Neg	2 acute ulcers
Kk	10	Neg	Neg	2 chronic perf ulcers
LL	8	Neg	Neg	Neg
MM	8	Neg	Neg	Neg
O	7	Neg	Neg	Neg
P	5	Neg	3 acute ulcers	1 acute ulcer
Q	11	Erosions	Neg	Neg
R	7	Neg	2 acute ulcers	Neg
S	12	Neg	Neg	2 acute ulcers
T	5	Neg	Neg	Neg
U	14	Erosive gastritis	Neg	Neg
V	5	Neg	Neg	Neg

Each dog received 30 mg of histamine (base) in beeswax peanut oil once daily. Dog V received 30 mg once daily for thirty days and 30 mg twice daily for twenty three days. Dogs LL, MM and V were sacrificed. The other dogs died.

Summary: Five out of twelve dogs had pyloric and/or duodenal ulcers.

*The Effect of Histamine on 3-Week-Old Fundic Excisional Ulcers*—(See Table II and Fig 1) Four out of five dogs succumbed to ulcers of the duodenum. In each dog the fundic excisional ulcer as well as the gastrostomy were completely healed as evidenced by scar contracture. It is to be considered that histamine-beeswax ulcer seldom, if ever, occurs in the fundus of the stomach.

Fig 1—The excisional ulcer of the fundus was made three weeks prior to starting daily injections of histamine in beeswax for three days. The animal died as a result of perforation of the duodenal ulcer.

TABLE II INCIDENCE OF ULCERS IN DOGS IN WHICH DAILY INJECTIONS OF HISTAMINE IN BEESWAX WERE BEGUN THREE WEEKS AFTER EXCISING A PIECE OF FUNDIC MUCOSA

DOG	SURVIVAL TIME (DAYS)	EXCISION ULCER	GASTROS TOMY	FUNDUS	PYLOPUS	DUODENUM
A	4	Healed	Healed	Neg	Neg	5 large nonperf ulcers
B	34	Healed	Healed	Neg	Neg	Severe duodenitis
C	4	Healed	Healed	Neg	Neg	1 large ulcer
D	3	Healed	Healed	Neg	Neg	1 chronic ulcer
E	3	Healed	Healed	Neg	Neg	1 large perf ulcer

Each dog received 30 mg of histamine (base) once daily. Dog B was sacrificed; the remaining dogs died.

Summary: Four out of five dogs had duodenal ulcers. In all cases the excisional ulcer and gastrostomy were completely healed.

*The Effect of Histamine on 3 Week Old Pyloric Excisional Ulcers*—(See Table III and Fig. 2) Seven out of twelve dogs had ulcers of the pylorus and/or duodenum. In every instance the excisional ulcer was completely healed and did not reulcerate as a result of histamine administration. The incomplete healing of two of the gastrostomy wounds was probably due to the use of non-absorbable suture material in closing the wound. The fact that ulcerations did occur in areas immediately adjacent to the healed ulcer is strong evidence of the local resistance of the healed ulcer.

Fig. 2—The excisional ulcer was made three weeks before the daily injections of histamine in beeswax were started. The animal was sacrificed after twelve days of injections because it was moribund. Note that ulcers and erosions occurred immediately adjacent to the healed ulcer but spared the scar itself.

#### DISCUSSION

On mere speculation, a healed ulcer might be expected to be more susceptible than adjacent normal mucosa to injury from histamine and gastric hypersecretion. Certainly present day concepts hold that the 'recurrence' of peptic ulcer in a patient usually represents the breaking down of the old ulcer site rather than the formation of an ulcer at a new site. The evidence of the increased resistance of a recently healed fundic or pyloric excisional ulcer which is provided by the present studies is subject to several interpretations.

TABLE III INCIDENCE OF ULCERS IN DOGS IN WHICH DAILY INJECTIONS OF HISTAMINE IN BEESWAX WERE BEGUN THREE WEEKS AFTER EXCISING A PIECE OF PYLORIC MUCOSA

DOG	SURVIVAL TIME (DAYS)	EXCISION\ ULCER	GASTROSTOMY	FUNDUS	PYLORUS	DUODENUM
F	28	Healed	Healed	Neg	Neg	Neg
G	6	Healed	Healed	Erosions	Erosions	1 acute ulcer
H	28	Healed	Healed	Neg	Neg	Neg
I	28	Healed	Healed	Neg	Neg	Neg
X	55	Healed	Incompletely healed	Neg	3 acute ulcers	Neg
Y	22	Healed	Healed	Neg	1 perf ulcer 1 small ulcer	Neg
Z	28	Healed	Healed	Neg	Neg	Severe duodenitis
EE	1	Healed	Healed	Neg	Neg	Neg
FF	14	Healed	Healed	Erosions	Erosions	Healed perf ulcer
GG	1	Healed	Incompletely healed	Neg	Multiple acute ulcer	Neg
HH	12	Healed	Healed	Neg	Multiple acute ulcer	Neg
II	4	Healed	Healed	Neg	1 large perf ulcer	1 chronic ulcer

Dogs F, H I X Z and HH were sacrificed the remainder died

Summary Seven out of twelve dogs had ulcers of the pylorus and/or duodenum All excisional ulcers were completely healed

One consideration is that a recently healed ulcer may have cells which are more resistant to damage. This may be due either to an inherent property of the epithelial cells or to the vascularity of the underlying granulation tissue.

The studies of others whose work has already been cited have shown that the fresh unhealed excisional ulcer is more susceptible than the surrounding normal mucosa to histamine induced ulceration. Our studies show that sometime during the healing process this increased susceptibility is reversed, resulting in a greater than normal resistance of the healed ulcer.

It is probable that human peptic ulcers are often not completely healed and so do not reach the stage of increased resistance. If the findings of this study should prove to be applicable to human peptic ulcer disease, they will have important implications for therapy. Thus with vigorous and prolonged ulcer therapy to insure complete healing, the incidence of apparent or real recurrence might be greatly lessened.

#### CONCLUSION

Three-week-old, healed fundic and pyloric excisional ulcers do not break down and reulcerate when histamine-beeswax is given although ulcer formation occurs in the adjacent normal mucosa of the pyloric portion of the stomach and duodenum.

# CONCENTRATION OF FREE VALINE, TRYPTOPHANE, AND HISTIDINE OF PLASMA OF YOUNG AND OLD INDIVIDUALS, DETERMINED WITH THE MICROBIOLOGIC METHOD

PHILIP ACKERMANN, PH D , LILLI HOFSTATTER, AND WILLIAM B KOUNTZ, M D  
ST LOUIS, MO

THE microbiologic method for determining essential amino acids has been used quite frequently for the analyses of protein of various sources<sup>2</sup> with techniques varying as to type of media and bacteria employed<sup>3</sup>. Published data on the free essential amino acids in the blood plasma of normal individuals as determined with the microbiologic technique are still scarce. Hier and Bergeim<sup>1</sup> reported the concentrations of ten essential free amino acids in the plasma of thirty-three normal young individuals, nine of them being women. These authors used *Leuconostoc mesenteroides* for the determination of histidine and *Lactobacillus arabinosus* for tryptophane and valine.

The use of more than one type of bacterium requiring also a larger number of media becomes inconvenient whenever the optimal determination of several amino acids is desired. *L. mesenteroides* has been suggested as possibly suitable for the determination of a larger number of amino acids than employed so far, since it was found to require sixteen amino acids for optimal growth<sup>4</sup>. Up to the present, however, we have found no publications in which *L. mesenteroides* was used in the determinations for valine and tryptophane, but it was employed successfully for histidine<sup>1, 4</sup> and others.

We were particularly interested in investigating whether the concentrations of free essential amino acids of the plasma in man are maintained throughout life. Because of the scarcity of data on normal subjects in the literature and as the use of *L. mesenteroides* was extended to the determination of valine and tryptophane our results on old individuals were compared with those on young subjects established in our laboratory with the same techniques.

## METHOD AND MATERIAL

Our subjects included twenty-seven young and twenty-three old individuals. The young subjects were mainly hospital employees who were in good health. The old individuals were inmates of the St. Louis City Infirmary Hospital whose ages ranged from 52 to 88. None of the patients was acutely ill at the time the tests were performed, but all had chronic diseases often found associated with old age. Their clinical diagnoses included generalized arteriosclerosis, arteriosclerotic heart disease, degenerative arthritis, senile psychosis, old cerebral thrombosis, and old bone fractures.

From each of the subjects in the basal state, 50 ml of blood were withdrawn, using heparin as the anticoagulant. The plasma was separated within one hour and tungstic acid filtrates were prepared as described by Hier and Bergeim. We used *L. mesenteroides*

From the Division of Gerontology, Washington University of Medicine and the St. Louis City Infirmary Hospital.  
Amino acids courtesy of Merck & Co. Inc. Rahway, N. J.  
Received for publication Sept. 30, 1948.

for all subjects with the medium D of Dunn and co workers<sup>4</sup> in the determinations for valine, tryptophane and histidine. In addition in fourteen of the young individuals valine and tryptophane was also determined with *I. arabinosus* in the medium described by Henderson and Snell<sup>6</sup>.

The amino acids and some salts for the two different media were weighed in substance for each determination. Vitamins purines and the salts A and B made up as described by Dunn and associates<sup>4</sup> were added in solution. The procedure was followed in essentially the same way as described by Dunn and co workers<sup>4</sup> and Stokes and co workers<sup>5</sup> with 1 ml portions of medium for each sample. However for greater accuracy the titrations were carried out potentiometrically. Further after completion of the incubation period, the samples were stored in ice to check further growth during the time required for titrating.

### RESULTS

Table I shows the concentration of valine, tryptophane and histidine expressed in micrograms per milliliter of plasma in young and normal individuals. All the determinations were performed with *I. mesenteroides*.

Parallel studies with *L mesenteroides* and *L arabinosis* for valine and tryptophane showed good agreement, as may be noted in Table II. Small differences found in some of the determinations were within the error limit. The differences of the means were not significant, although the determinations with *L arabinosis* yielded slightly higher values for valine. We found, however, better agreement on various levels of the slope in the determinations that were carried out with *L mesenteroides* than with those with *L arabinosis*.

The concentrations of free valine, tryptophane, and histidine in old individuals determined with *L mesenteroides* are recorded in Table III.

## DISCUSSION

The results obtained in young people with *L. mesenteroides* for valine and tryptophane compare well with those obtained in the literature that were carried out with *L. arabinosis*. They were somewhat higher in the men for valine (see Table IV), the mean being  $29.6 \pm 4$   $\gamma$  per milliliter while Hjer and Bergheim reported  $28.3 \pm 3.4$   $\gamma$  per milliliter. The concentration of tryptophane averaged for the young group  $11.8 \pm 2.1$   $\gamma$  per milliliter, compared with the literature value of  $10.8 \pm 2.1$   $\gamma$  per milliliter. Histidine determined with the same bacterium gave a mean identical with that obtained by Hjer and Bergheim of  $14.2 \pm 2.2$   $\gamma$  per milliliter.

TABLE IV. COMPARISON OF RESULTS OF AMINO ACIDS OF OUR LABORATORY WITH THOSE OF HJER AND BERGHEIM (REPORTED AS MICROGRAMS PER MILLILITER OF PLASMA)

for valine. The mean for valine in the young normal subjects was  $29.6 \pm 4$   $\gamma$  per milliliter, while it comprised in the old individuals only  $24.6 \pm 3.1$   $\gamma$  per milliliter, the difference being 5  $\gamma$  per milliliter of plasma. The standard error was calculated<sup>9</sup> and found to be 1.0  $\gamma$  per milliliter.

## SUMMARY

1. The results obtained with *L. mesenteroides* in determining tryptophane and valine are comparable with those determined with *L. arabinosis*.

TABLE II AGENIZED PROTEIN SUPPLEMENTS TO ADULTS' NORMAL DIET OF 2,500 3,000 CALORIES PER DAY

GLUTEN CEREAL		CHOCOLATE MILK	
100 Gm	cooked cereal	1 Glass	milk
15 Gm	gluten (225 Gm Agene per cwt)	1 Tablespoon	chocolate syrup
25 Gm	hot water	25 Gm	casein (20 Gm Agene/cwt)
GLUTEN MUFFINS (Makes 12 muffins)			
	1 Yeast cake		
	1 Cup milk		
	1 Teaspoon salt		
	2 Teaspoons butter		
	1 Cup bread flour (20 Gm Agene/cwt)		
	190 Gm gluten (225 Gm Agene/cwt)		
	1 Slightly beaten egg white		
1 Helping cereal	15 Gm gluten	12 5 Gm	protein
1 Muffin	15 Gm gluten	12 5 Gm	protein
	15 Gm flour	1 9 Gm	protein
1 Glass choc milk	25 Gm casein	23 7 Gm	protein
Each adult patient regularly consumed			
		1 Helping cereal	
		1 Muffin	
		3 Glasses chocolate milk	
each day as a supplement to normal diet (98 Gm Agenized protein)			

within normal limits. These subjects had noted no untoward symptoms while on the diet. One subject gained almost thirty pounds and the other ten pounds in weight during the experimental period.

#### DISCUSSION OF RESULTS

Previous experiments have shown that the greater the amount of Agene treated material in the ration or the more heavily it is treated the more rapid is the onset of the gross and electroencephalographic abnormalities in dogs, Newell and co-workers<sup>4</sup>. One would expect the same to be true in man if he were susceptible to a possible toxic factor in the Agenized material.

Flour bought on the market is usually treated with 1.25 to 2.5 Gm of Agene per hundredweight. Not only were the experimental diet supplementations more heavily treated with Agene, but also as much as 100 Gm of highly Agenized protein (225 Gm Agene per hundredweight) were consumed in addition to the normal diet which contained wheat products treated with commercial levels of Agene. We suggest from these facts that, by analogy with the rations used to produce canine epilepsy, the diets used in these human observations should be an adequate test of the susceptibility of man to a similar toxic factor in Agenized material.

None of the nineteen patients (Table III) who consumed this highly Agenized diet showed any clinical or electroencephalographic evidence of the development of epilepsy. Nor did the five epileptic patients show any demonstrable increase in the number of epileptic seizures or any significant increase in the abnormality present in their electroencephalograms.

# DISCUSSION

The results obtained in young people with *L. mesenteroides* for valine and tryptophane compare well with those obtained in the literature that were carried out with *L. arabinosus*. They were somewhat higher in the men for valine (see Table IV), the mean being  $29.6 \pm 4 \gamma$  per milliliter while Hjer and Bergeim reported  $28.3 \pm 3.4 \gamma$  per milliliter. The concentration of tryptophane averaged for the young group  $11.8 \pm 2.1 \gamma$  per milliliter, compared with the literatures' value of  $10.8 \pm 2.1 \gamma$  per milliliter. Histidine determined with the same bacterium gave a mean identical with that obtained by Hjer and Bergeim of  $14.2 \pm 2.2 \gamma$  per milliliter.

The standard error was calculated<sup>9</sup> and found to be  $1.0 \gamma$  per milliliter.

# SUMMARY

1. The results obtained with *L. mesenteroides* in determining tryptophane and valine are comparable with those determined with *L. arabinosus*.

2 Determinations of free valine and tryptophane of the plasma in twenty-seven normal young individuals yielded means of  $29.6 \pm 4.0$   $\gamma$  per milliliter and  $11.8 \pm 2.1$   $\gamma$  per milliliter respectively. This compares well with findings reported previously by other authors.

3 The concentrations of free tryptophane and histidine in the blood plasma of elderly individuals were found not to differ significantly from those of young normal subjects, while the concentration of free valine is lower in old individuals, at least in those who are afflicted with degenerative diseases.

# STUDIES ON HUMAN SUBJECTS RECEIVING HIGHLY AGENIZED FOOD MATERIALS

G. W. NEWELL, PH.D. T. C. THACKSON, M.D. W. L. GILSON, M.D.  
S. N. GERSHOF, M.S. AND C. A. LARSEN, PH.D.  
MADISON, WIS.

FOR over a quarter of a century nitrogen trichloride (commonly known as Agene) has been used by the milling industry as a maturing agent for white flour. The apparent superiority of Agene over other agents and the ease with which this gaseous component can be handled have made it the most common maturing agent for white flour.

In December of 1946 Mellanby<sup>1</sup> first reported that running fits could be precipitated in dogs when they were fed diets containing flour treated with nitrogen trichloride. As far back as 1937, Melnick and Cowgill<sup>2</sup> reported that the alcohol soluble moiety of wheat protein, gliadin caused convulsions when fed to dogs. Wagner and Elvehjem<sup>3</sup> in 1944 reported that wheat gluten, the water insoluble portion of wheat protein produced running fits when added to an otherwise complete ration. As little as 10 per cent wheat gluten in a purified ration induced these attacks in twenty five to thirty days while increased amounts of the protein brought on seizures in proportionally shorter periods. Further investigation by Newell and co-workers<sup>4</sup> after Mellanby's report showed that Agene but none of the other commercial maturing and/or bleaching agents would react with flour or gluten to produce the toxic factor which caused fits. In order to induce fits readily in dogs flour was included at 84 per cent of the ration.

The American diet rarely contains more than 30 per cent of flour. Five dogs were placed on rations which contained 30 per cent of flour treated with commercial levels of Agene. These animals were fed the rations for periods of from ten to twelve months and all remained healthy with no indication of running fits. Electroencephalograms were taken on these animals after they had been on experiment for seven to nine months and all showed normal tracings. Thus it was apparent that in order to produce any effect in dogs it was necessary to feed the commercially treated flour at excessive levels or the flour had to be treated with large quantities of Agene.

The susceptibility of other species of animals has been tested, and while none were quite as sensitive as the dog, the convulsive state was readily induced by feeding highly Agenized flour rations to rabbits, cats, mink, and

We are indebted to Dr. H. K. Parker and Mr. Meade C. Harris of the Wallace and Tiernan Company for preparing many of the Agenized food materials.

We wish to thank Miss Ruth S. Dicke and Miss Ruth Flummertelt for their help in preparing diets for the human subjects. Miss Phyllis Helmer, Miss Hulda Gleschen and Miss Genevieve Gulan for their assistance in recording the electroencephalograms.

Received for publication October 14, 1948

ferrets No effect was observed when Agenized rations were fed to rats, chicks, or guinea pigs Monkeys fed highly Agenized flour rations showed abnormal electroencephalograms, but no gross changes Silver and associates<sup>6</sup> also reported abnormal electroencephalograms and stated that monkeys fed highly Agenized rations developed asynergy, weakness of the extremities, and sluggishness in response to irritating stimuli in comparison with normal animals Radomski and co-workers,<sup>7</sup> however, observed no adverse conditions when monkeys were fed highly Agenized rations for as long as fifty-four days

It was reported in 1946<sup>8</sup> that electroencephalograms taken on dogs fed Agenized wheat gluten showed brain wave patterns similar to those seen in cases of idiopathic epilepsy in man Since the convulsions and electroencephalographic patterns of these dogs showed a close analogy to human epilepsy the question arose whether Agenized wheat products play any part in the incidence of human epilepsy The publication of Mellanby's article at this time added emphasis to the problem Articles have appeared in the lay press implying that Agene treated flour is an important cause of human epilepsy even though no direct evidence has been published to support such statements

In an effort to answer this question, children and adults have been fed diets which contain normal and excessive amounts of Agenized food products

#### METHODS AND RESULTS

The children, 5 to 16 years of age, were hospital patients, the adults were students at the University Some subjects had no previous history of epilepsy, while five patients had had seizures from time to time After a physical examination by a member of the medical staff each patient was placed on a normal diet for a week or more, during which time several control electroencephalograms (EEG) were taken After the characteristic electroencephalogram of each patient had been determined, supplements of white flour, whole wheat flour, wheat gluten and casein treated with Agene (3 to 225 grams per hundredweight) were incorporated into each meal fed the patients The foods treated with high levels of Agene were included in such items as cereal, chocolate milk, muffins, bread, gravy, and meat patties Although the patients knew an experimental diet was under test, they did not know what was being used or what effect the diet might have upon them Electroencephalograms were taken every three to four days while the Agenized diet was fed Some of the subjects were continued on the diet for periods as long as 210 days The children were offered 100 to 150 Gm of Agenized food products per day, but the consumption was not constant due to the unpalatability of the food supplements On the whole, the children consumed 65 to 75 per cent of the Agenized foods offered The adults were fed Agenized foods on the basis of their protein content and, in general, attempts were made to include sufficient quantities of the treated materials to supply 100 Gm per day Since palatability had been increased as a result of previous tests in feeding the chil-

dren and because adults were easier to work with, all the Agenized foods offered were consumed by these subjects except two patients (that is C M and M B) who developed nausea.

In Table I are summarized the Agenized food supplements offered to the children. Consumption in terms of Agenized protein ranged from 40 to 114 Gm per day depending upon the acceptance of the foodstuffs by the patients. The flour was treated with 3 Gm of Agene per hundred pounds which is two times the amount of Agene used to treat flour commercially. The gluten was made from flour treated with 4 Gm of Agene per hundred pounds (which is equivalent to 40 Gm of Agene per hundred pounds of gluten). Thus the children received daily twenty three to thirty times as much active material as might be present in a normal diet.

TABLE I AGENIZED FOOD SUPPLEMENTS TO CHILDREN'S NORMAL DIET OF 1500-1800 CALORIES PER DAY

GLUTEN CEREAL		CHICKEN MEAT PATTIES	
100 Gm cooked cereal		75 Gm raw ground meat	
25 Gm gluten (40 Gm Agene per cwt)		25 Gm gluten (40 Gm Agene per cwt)	
25 Gm hot water		Milk to moisten	
GLUTEN MUFFINS (Makes 12 muffins)			
	1 Yeast cake		
	1 Cup milk		
	1 Teaspoon salt		
	2 Teaspoons butter		
	1 Cup bread flour (3 Gm Agene/cwt)		
	180 Gm gluten (40 Gm Agene/cwt)		
	1 Slightly beaten egg white		
1 Helping cereal	25 Gm Gluten	21 Gm protein	
1 Meat patty	25 Gm gluten	21 Gm protein	
1 Muffin	15 Gm gluten	12.5 Gm protein	
	15 Gm flour	1.9 Gm protein	
Each child fed	1 Helping cereal		
	1 Meat patty		
	3.5 Muffins		
each day as a supplement to normal diet (80-114 Gm Agenized protein)			

Table II presents a summary of the Agenized protein supplements consumed by the adults while on the experimental diet. All subjects ate about 100 Gm of highly Agenized protein (that is treated with 20 to 225 Gm Agene per hundredweight) per day. The Agene treatment of the material fed to human subjects of the present experiment was twenty two times more than that of the normal diet. A total of nineteen patients have been tested thus far and the results are presented in Table III.

In addition two of the adults (R G H and A D S) were subjected to more intensive examinations after they had been on the Agene diet for a period of seven months. The gastrointestinal x-ray study was completely negative. Erythrocytes, leucocytes, and differential blood counts as well as urinalysis, blood sugar, nonprotein nitrogen, and serum protein values were

within normal limits. These subjects had noted no untoward symptoms while on the diet. One subject gained almost thirty pounds and the other ten pounds in weight during the experimental period.

#### DISCUSSION OF RESULTS

Previous experiments have shown that the greater the amount of Agene treated material in the ration or the more heavily it is treated the more rapid is the onset of the gross and electroencephalographic abnormalities in dogs, Newell and co-workers<sup>4</sup>. One would expect the same to be true in man if he were susceptible to a possible toxic factor in the Agenized material.

Flour bought on the market is usually treated with 1.25 to 2.5 Gm of Agene per hundredweight. Not only were the experimental diet supplementations more heavily treated with Agene, but also as much as 100 Gm of highly Agenized protein (225 Gm Agene per hundredweight) were consumed in addition to the normal diet which contained wheat products treated with commercial levels of Agene. We suggest from these facts that, by analogy with the rations used to produce canine epilepsy, the diets used in these human observations should be an adequate test of the susceptibility of man to a similar toxic factor in Agenized material.

None of the nineteen patients (Table III) who consumed this highly Agenized diet showed any clinical or electroencephalographic evidence of the development of epilepsy. Nor did the five epileptic patients show any demonstrable increase in the number of epileptic seizures or any significant increase in the abnormality present in their electroencephalograms.

TABLE III CLINICAL HISTORIES AND RESULTS OF FEEDING HIGHLY AGENIZED DIETS TO HUMAN SUBJECTS

NAME	SEX	AGE (YR)	DIAGNOSIS	CORTISOL FTG 6/sec and 8 12/sec waves	TIME ON DIET (DAYS)	RESULT
L A L	M	19	Normal	6/sec and 8 12/sec waves	60	No change

A E S	M	20	No disease	Normal, 8 12/sec waves	210	No change in EEG or clinical con- dition except gain in weight
C M M	M	22	No disease	Normal, 8 12/sec waves	25	No change, lost weight

Susceptibility to the development of epilepsy from the possible toxic effect of the Agenized material would be expected to vary. One patient (M F T) (Table III) who was clinically normal, having no history of epileptiform seizures, had periodic bursts of slow waves suggesting that he had the genetic or constitutional background for the development of seizures. Since he seemed to be an ideal subject for testing the effect of the diet, he was kept under observation for nine months and was placed on the Agene diet for two separate periods. There was no consistent relationship between his abnormal electroencephalogram and the time on the diet. At no time did he develop any suggestion of epileptic seizures though from the appearance of his electroencephalogram one would have expected him to be especially susceptible. The lack of effect of the Agene diet on the normal individuals, those with unrelated illness, and those with epilepsy in the present experiments does not eliminate the possibility that there may be some patients with an idiosyncrasy or an allergy to the Agenized products. Perhaps patients with a known allergy for wheat products should be investigated further in this manner as should those with subclinical epilepsy.

The question arises whether changes would be observed if the Agene diet were continued over a longer period of time. By comparison with dogs in which the characteristic electroencephalographic abnormality and convulsions appear within three or four days it is evident from Table III that the duration of the trial has been adequate. It has been intimated that a lifetime consumption of bread made from flour treated with Agene may cause disturbance of the nervous system and might induce such things as duodenal ulcers (Silver and co-workers<sup>6</sup>). It might be difficult to disprove such a theory as far as the other diseases mentioned by these authors are concerned, but it is well known that epilepsy has been common since the dawn of history (Temkin<sup>9</sup>). There is no evidence of an increase in the incidence of epilepsy in the past quarter of a century during which the use of Agenized flour has become widespread. As noted previously, in our patients (A E S and R G H) there were no clinical symptoms of gastric or duodenal ulcers, and the gastrointestinal x-ray examinations were negative after the patients had been on the diet for seven months.

The negative results of this study in human beings confirms the species specificity of the toxic effects of Agenized protein indicated by Newell and associates,<sup>4</sup> that is, positive results were obtained in dogs, cats, and rabbits, and no effect was observed in rats, chicks, or guinea pigs. The effect on monkeys was rather doubtful. This variation in the response of the different species suggests a difference in the metabolism of the material in these different animals. Possibly there is preferential absorption or a detoxification mechanism present in man and the other nonsusceptible animals which is not present in the dog. Analogous metabolic differences are well known.

#### SUMMARY

Nineteen patients, including five with epilepsy, have been fed a diet containing twenty-two to thirty times the amount of Agenized material contained

in a normal diet. Physiological, neurological and electroencephalographic examinations have failed to disclose any abnormal changes as the result of such a diet and none of the patients has developed epileptic seizures as a result of this diet. The results are discussed in relation to previous studies which have shown that Agenized protein produces an epileptic condition (running fits) in dogs and other animals. It is suggested that this species difference in response to Agenized material represents a species difference in absorption or detoxifying mechanisms.

## A COMPARISON OF THE BROMSULFALEIN AND ROSE BENGAL TESTS

LEE MONROE, M D , AND JAMES HOPPER, JR , M D  
SAN FRANCISCO, CALIF

DYE excretion tests have been used for over twenty-five years as an index of liver function. Today the bromsulfalein test as introduced by Rosenthal and White<sup>1</sup> and modified by Mateer and co-workers<sup>2</sup> and the rose bengal test as done by Althausen, Biskind, and Keri<sup>3</sup> are the most widely used to measure hepatic reticulo-endothelial activity. The bromsulfalein\* test has been subjected to numerous modifications, but it is generally accepted that the administration of 5 mg per kilogram intravenously as first suggested by Macdonald<sup>4</sup> has increased the sensitivity of the test. Conservative normal values for forty-five and sixty minute specimens are 5 and 2 per cent respectively and are in accord with the work of Mateer, who designates 4 per cent as the upper normal for the retention at forty-five minutes. We have accepted a slightly higher value for our forty-five minute specimen so as to eliminate all possibility of false positive results. We have found that when a curve is prepared on semilogarithmic paper from accurately timed specimens taken from normal patients, the resulting graph closely approximates a straight line until very low values are reached (below 1 per cent). Several such curves are shown in Fig 1. It can be noted that the occasional line which reaches 1 per cent at the end of an hour will pass close to 4 per cent in forty-five minutes. For this reason, a slightly higher normal value is used for the forty-five minute sample and a confirmatory sample is drawn at sixty minutes.

The rose bengal test is performed by the intravenous administration of 10 cc of a 1 per cent solution of diiodotetrachlorofluorescein. A two minute sample is withdrawn and represents the 100 per cent concentration. An eight and sixteen minute sample are taken and the amount of the dye retained is determined by the hand spectriograph. Althausen and co-workers give 55 and 35 per cent respectively as the upper limits of normal for the two samples.

The rose bengal test was developed in an era when the 2 mg test of Rosenthal and White was in vogue and was considered to be of comparable sensitivity and perhaps of greater specificity. The series here presented was done in an effort to determine whether the rose bengal test is as sensitive as the 5 mg test of Mateer and associates.

Aided in part by funds from the Christine Breon Donation  
From the Division of Medicine University of California Medical School  
Received for publication Oct 8 1948

\*Bromsulfalein for making the standard curves was donated by Hynson Westcott Dunning Inc Baltimore Md

Fig 1 --Bromsulfalein disappearance in normal subjects

#### METHODS

The bromsulfalein concentrations were determined by the use of the Evelyn photo electric colorimeter after the method described by Bradley.<sup>5</sup> The rose bengal determinations were done after the method of Althausen and associates<sup>3</sup> using the hand spectrograph. The patients used in this series were all suspected of having liver dysfunction and many had clinical evidence of hepatic impairment.

#### RESULTS

The results of this study are found in tabular form in Table I

\*Denotes patients with positive BSP and negative rose bengal tests

#### DISCUSSION

Of the twenty-four patients suspected of having liver dysfunction, ten (41.7 per cent) had positive BSP tests and negative rose bengal determinations. One patient (No 22) had a positive value for the sixteen minute sample of rose bengal—the eight minute sample and the BSP test were normal. There were several patients e.g. Nos 18 and 8, who showed a strongly positive BSP and borderline positive rose bengal values.

Technically the BSP is the simpler of the two tests. The readings as obtained on the Evelyn photoelectric colorimeter have little element of individual error and are not significantly influenced by hemolysis. Bromsulfalein has several disadvantages. It is expensive. Moreover, unlike rose bengal, it is not eliminated entirely by the liver and spillage occurs via the kidney when high blood levels are encountered, thereby tending to falsify the test in favor of better than actual function in cases with severe pathologic retention. When BSP is extravasated, it can cause a severe chemical cellulitis with the appearance of brown swelling and violaceous coloration.

Rose bengal is relatively cheap and has the advantage of specificity, but also has some disadvantages. The patients must be warned to stay out of direct sunlight after the test because photosensitivity is apt to occur. In addition cells hemolyze in vitro in the presence of rose bengal when they are exposed to direct sunlight. The appearance of red stools after the test although frightening to the patient cannot be deemed a disadvantage. The visual spectrophotographic matching of the absorption bands in the determination

of rose bengal is sometimes difficult particularly when bands of hemoglobin are present in sufficient strength to interfere. The last most important difficulty might perhaps be eliminated by analysis with a spectrophotometer.

This series can be criticized because of the fact that liver function might have changed during the period which elapsed during the performance of the tests. However, a large discrepancy favoring the BSP test existed when the performance of the two tests was only a few days apart. Further this tendency was not influenced by doing one test or the other first, the series being about equally divided in this respect. The lack of correlation between the two tests and the consistency with which the BSP was positive in the presence of a negative rose bengal is a strong indication that the BSP is a more sensitive procedure. However the sensitivity of a test does not necessarily reflect its utility and further work may clarify the relative value of these procedures.

#### SUMMARY

A series of twenty four patients with suspected liver disease is presented in which the bromsulphalein and rose bengal tests are compared. Forty one and seven tenths per cent of the patients with normal rose bengal tests had positive BSP determinations. The 5 mg BSP test appears to be more sensitive than the rose bengal test as determined by the visual spectriograph.

## OBSERVATIONS ON THE HISTAMINE CONTENT OF THE CEREBROSPINAL FLUID IN MAN

IRA J. JACKSON, M.D., M.Sc., AND BRAM ROSE, M.D., Ph.D.  
MONTREAL, CANADA

IT IS generally agreed by most workers that 80 to 90 per cent of the blood histamine content is held within the white cell elements,<sup>1,2</sup> but there is considerable controversy as to which of the white cells carries this bound or intracellular histamine. Some believe that the polymorphonuclear eosinophile is responsible,<sup>3</sup> whereas others consider that the platelets are mainly involved.<sup>4</sup>

Since cerebrospinal fluid may contain polymorphonuclear or lymphocytic cells as a result of meningeal irritation, it was thought that a study of the histamine content of such cerebrospinal fluid, as well as that of normal samples, might provide some evidence as to which type of cell is responsible for carrying histamine.

### METHODS

Cerebrospinal fluid collected by lumbar puncture in the case of normal subjects, or directly from the ventricle as well as by tap in the neurosurgical patients, was extracted for histamine by the method described by Code for blood.<sup>5</sup> Five cubic centimeter samples of the CSF were used. The extracts were assayed on the isolated, atropinized guinea pig ileum preparation suspended in Tyrode solution at 38° C. All results are expressed as histamine base in gamma per 100 cubic centimeters.

### SUBJECTS

The two groups of patients studied were from the neurological and neurosurgical services of the Royal Victoria Hospital and the Montreal Neurological Institute. The first group, comprising nineteen patients who presented no signs of meningeal irritation, served as controls. In all, routine examination of the CSF showed a cell count of 0 to 5 per cmm, total protein of 20 to 45 mg per cent, negative Wassermann, and the findings were considered normal.

The second group was made up of fifteen patients in whom abnormal CSF findings were observed and on which twenty-one histamine determinations were made. In twelve of these patients, the CSF fluid was obtained during the postoperative period. Six patients had the postoperative course complicated by an acute aseptic recurrent meningitis, a condition which follows intracranial surgery and was described by Finlayson and Penfield in 1941.<sup>6</sup> They observed that after the removal of a cerebral neoplasm or atrophic epileptogenic lesion, a blood clot is left behind which undergoes degeneration and liquefaction in the operative cavity. The breakdown products of the blood clot accumulate and are discharged into the subarachnoid space. Here they irritate its lining, resulting in an outpouring of leucocytes. This syndrome is characterized by repeated bouts of meningeal irritation which are associated with an increase in the number of leucocytes and protein values in a sterile spinal fluid. Patients 26 and 27 (see Table II) had their postoperative course complicated by a bacterial meningitis (*Bacillus coli* and hemolytic streptococci). A glioma of the third ventricle and a cerebellar cystic astrocytoma respectively were removed. The spinal fluid in three patients (26, 27, and 28) was withdrawn during the early postoperative period at which time the fluid showed a mild aseptic reaction as evidenced by an increase in the leucocyte count and protein value. This is a fairly

common finding postoperatively and is usually of no consequence. The four nonoperated patients (31, 32, 33, and 34) presented abnormal CSF values resulting from their underlying intracranial pathology as shown in Table II.

18 B	M	Normal	Clear and colorless	—	0.9
19 W C	M	Normal	Clear and colorless	—	0.8
					Average 0.97

The cell count in the spinal fluid ranged from 0 to 7 lymphocytes per cubic millimeter.

†The spinal fluid was taken during this patient's postoperative period.

## RESULTS

The values obtained in the group of control cases are shown in Table I. It will be seen that the average histamine content of the CSF is 0.97  $\gamma$  per 100 cc, with variations of 0.2 to 3.0  $\gamma$  per 100 cubic centimeters. The highest value 3.0  $\gamma$  per 100 cc was found in the CSF of a patient with trigeminal neuralgia. It will be noted that all the CSF specimens from this group were clear and colorless with the exception of that from Patient 7.

In the second group of cases, twenty-one samples of CSF were obtained for analysis. The results are shown in Table II. These samples varied in appearance from colorless to xanthochromic and from clear to turbid. The total protein was increased in all specimens, the highest value being 854 mg per cent (Patient 20). Each sample moreover, had an increase in cell count with the exception of that from Patient 34, in which only the protein value was slightly elevated. The number of cells ranged from 0 to 11,000 per cubic millimeter. These were either wholly lymphocytic or polymorphonuclear or occasionally both. In a few specimens red blood cells were found. It will be observed that the average histamine content of the CSF in this group of patients was 1.43  $\gamma$  per 100 cc as compared with 0.97  $\gamma$  per 100 cc for the controls.

# OBSERVATIONS ON THE HISTAMINE CONTENT OF THE CEREBROSPINAL FLUID IN MAN

IRA J JACKSON, M D, M Sc, AND BRAM ROSE, M D, PH D  
MONTREAL, CANADA

IT IS generally agreed by most workers that 80 to 90 per cent of the blood histamine content is held within the white cell elements,<sup>1, 2</sup> but there is considerable controversy as to which of the white cells carries this bound or intracellular histamine. Some believe that the polymorphonuclear eosinophile is responsible,<sup>3</sup> whereas others consider that the platelets are mainly involved.<sup>4</sup>

Since cerebrospinal fluid may contain polymorphonuclear or lymphocytic cells as a result of meningeal irritation, it was thought that a study of the histamine content of such cerebrospinal fluid, as well as that of normal samples, might provide some evidence as to which type of cell is responsible for carrying histamine.

Patients 26 and 27 (see Table II) had their postoperative course complicated by a bacterial meningitis (*Bacillus coli* and hemolytic streptococci). A glioma of the third ventricle and a cerebellar cystic astrocytoma respectively were removed. The spinal fluid in three patients (26, 27, and 28) was withdrawn during the early postoperative period at which time the fluid showed a mild aseptic reaction as evidenced by an increase in the leucocyte count and protein value. This is a fairly

From the Department of Neurology and Neurosurgery of McGill University, The Montreal Neurological Institute and the McGill University Clinic Royal Victoria Hospital.  
Received for publication Oct 18 1948

The average histamine content of the CSF from the group with aseptic recurrent meningitis was 1.64  $\gamma$  per 100 cc, while the three specimens from the patients with bacterial meningitis averaged 1.87  $\gamma$  per 100 cubic centimeters. An average histamine content of 0.97  $\gamma$  per 100 cc of CSF was found in the group with early postoperative reactions, whereas only 0.87  $\gamma$  per 100 cc was found in the CSF of the patients who had not been operated on. The variations in these four subgroups correspond in general to the number of leucocytes present in the CSF and do not appear to be related to the amount of spinal fluid protein or the underlying pathology.

TABLE III

NUMBER OF CELLS IN CEREBROSPINAL FLUID PER CC	TYPE	HISTAMINE CONTENT OF CEREBROSPINAL FLUID ( $\gamma$ /100 cc)
11,000	I polymorph	3.0
9,000	I polymorph	1.6
6,000	I polymorph	2.0
2,100	P polymorphs	2.2
2,000	I polymorphs	3.0
1,500	I polymorph	0.8
1,015	P polymorphs	1.5
1,000	P polymorph	1.3
640	P polymorphs	0.5
260	Lymphocyte	1.0
200	Lymphocyte	2.0
120	Lymphocytes	2.0
83	Lymphocyte	0.8
40	Lymphocyte	2.0

In Table III the histamine values are arranged according to the descending order of cell counts. It will be observed that there is some correlation between the number of polymorphonuclear cells and the histamine content of the CSF but that this is far from constant. There seems to be little relationship between the histamine content and the lymphocyte count of the CSF although the histamine values are elevated.

## DISCUSSION

Blood plasma contains on the average 0.5  $\gamma$  histamine per 100 cc and it will be noted that this value is not dissimilar to that obtained for normal CSF. While the number of determinations in each group is small, it seems clear that an increase in the cell count of CSF is accompanied by an increase in its histamine content. From the results obtained, however, there does not appear to be much difference as to whether these cells are lymphocytes or polymorphonuclear in type. Studies on the histamine content of the blood of man have shown that for the most part highest values are found when immature myelogenous cells prevail such as in the myelogenous leucemias.<sup>7,8</sup> We have been unable to show that the eosinophile is per se the white cell responsible for carrying the blood histamine<sup>9</sup> since marked variations in the percentage of the eosinophiles in the blood of the same patient taken at different time intervals was not paralleled by similar changes in the blood histamine content.

It would appear that the elevated CSF histamine values observed in recurrent aseptic meningitis are not characteristic of this particular syndrome, but are merely a result of the white blood cells present in the spinal fluid, as evidenced by values obtained in other meningeal abnormalities. It is difficult to interpret the value of 3.0  $\gamma$  per 100 cc which was found in Patient 13 (Table I), since the cell count and protein values were within normal limits.

#### SUMMARY

1 The histamine content of the CSF was studied in a group of nineteen patients whose spinal fluid was normal and in a group of fifteen patients whose CSF was abnormal.

2 The average histamine content of normal CSF was found to be 0.97  $\gamma$  per 100 cc with variations of from 0.2 to 3.0  $\gamma$  per 100 cubic centimeters. Abnormal CSF was found to have an average histamine content of 1.43  $\gamma$  per 100 cc with variations of from 0.5 to 3.0  $\gamma$  per 100 cubic centimeters.

3 Some correlation between the number of cells present and the histamine content of CSF could be demonstrated. This was more marked for polymorphonuclears than for lymphocytes.

4 The underlying intracranial abnormality and increased CSF protein values did not appear to influence directly the histamine content of the spinal fluid.

We wish to thank Mrs. E. V. Harkness for carrying out the histamine assays.

JEROME W. CONN, M.D. LAWRENCE H. LOUIS, Sc.D., AND  
MARGARET W. JOHNSTON, PH.D.  
ANN ARBOR, MICH.

WITH THE TECHNICAL ASSISTANCE OF BETTY JOHNSON, B.S., JANE BLOOD, B.S.,  
AND ELIZABETH PINKHAM, B.S.

IN A PREVIOUS communication<sup>1</sup> it was reported that a typically diabetic state can be produced in man by the intramuscular administration of a purified preparation of adrenocorticotrophic hormone (A.C.T.H.). It was observed that loss of carbohydrate tolerance was not related to increased glyconeogenesis from protein. Severe negative nitrogen balance may accompany loss of carbohydrate tolerance induced by A.C.T.H. but the existence of one is not dependent upon the presence of the other.

It was reported further that a remarkably close correlation exists between loss of carbohydrate tolerance and the increased urinary excretion of uric acid which accompanies continued administration of A.C.T.H. It was suggested on the basis of a few determinations of blood glutathione done on one subject, that heightened intracellular production of uric acid and its intermediaries produced by A.C.T.H., together with a fall of the levels of glutathione and perhaps of other sulfhydryl bearing substances may impair functional activity of the beta cells of the islets of Langerhans.

The present report deals with experiments designed to explore further the relationship between loss of tolerance for carbohydrate, increased production of uric acid and changes in the levels of blood glutathione. Two normal men and a patient suffering from gout were used as the subjects of these studies. The procedure and chemical methods employed were the same as those described previously<sup>1</sup> with the exception that all determinations for urinary uric acid\* were performed according to the method of Buchanan, Block and Christman. Urinary "cortin" was determined by the method of Daughaday, Jaffe and Williams.<sup>12</sup>

The A.C.T.H.† used in this study was prepared‡ by a modification of the method of Sayers and co-workers.<sup>3</sup> The laboratory has supplied us with the properties of these materials (Table I). Because the diabetogenic potency of

EFFECT OF ACTH UPON BLOOD SUGAR AND GLUTATHIONE  
AND UPON URINARY SUGAR, NITROGEN AND URIC ACID  
(R S O 37 NORMAL SUBJECT)

Fig 1—ACTH during the first six days was from Lot 37-K G During the last two days Lot G 59703 was employed

Lot G-59703 was found to be considerably less than that observed for Lot 37-K G (although equal potency for the two preparations was observed for other metabolic responses), material from each lot was administered in consecutive periods to each of the three subjects. Thus, Subject D E received material from Lot G-59703 for six days and from Lot 37-K G on the seventh and eighth days of his ACTH period. Subject R S received Lot 37-K G for six days and Lot G-59703 on the seventh and eighth days. Subject E S (gout) received Lot 37-K G for three days and Lot G-59703 on the fourth and

fifth days of A C T H administration. In this way the factor of individual variation in responsiveness to A C T H was minimized and any changes in blood glutathione, urinary uric acid and urinary "cortin" associated with the induction of glycosuria by the lot possessing the more potent diabetogenic property were controlled by the material which had but a mild diabetogenic effect.

### RESULTS

All of the results dealing with blood sugar, carbohydrate tolerance, blood glutathione, urinary sugar, nitrogen and uric acid are shown graphically on Figs 1 through 6.

Fig 2—A C T H during the first six days was from Lot 37 K G. During the last two days Lot G 59703 was employed.

*Glycosuria and the Level of the Fasting Blood Sugar*—All three subjects developed glycosuria when given 52 mg (Armour Standard) per day of Lot 37 K G (Figs 1, 3 and 5). In Subject R S (Fig 1), 52 mg per day of Lot G 59703 maintained glycosuria initiated by Lot 37 K G but in Subject E S (Fig 5) the glycosuria disappeared when the switch was made. In Subject D L (Fig 3) no glycosuria occurred with 26 mg per day of Lot G 59703 but it did appear when the dose of this material was increased to 52 mg per

day. A great increase of glycosuria occurred abruptly when 52 mg per day of Lot 37-K G were given on the seventh and eighth days. It is clear that Lot 37-K G had the more intense diabetogenic effect.

Maximal twenty-four hourly glycosuria for the three subjects was 117 grams (D E), 138 grams (E S), and 280 grams (R S), the latter despite the administration of 100 units of protamine zinc insulin per day. Glycosuria was not accompanied by polyuria. Retention of sodium, chloride, and water<sup>4</sup> occurring simultaneously with the glycosuria tended to diminish urinary volume moderately.

Fig 3—A C T H during the first six days was from Lot G-50703. During the last two days Lot 37-K G was employed.

The maximal rise of the fasting blood sugar above the average base line value amounted to 47 per cent (D E), 37 per cent (E S), and 56 per cent (R S), the latter during administration of protamine zinc insulin.

**Carbohydrate Tolerance**—Subject R S (Fig 2) gave a typically diabetic response after five days of A C T H (Lot 37-K G). It should be noted that a total of 330 units of protamine zinc insulin had been administered during the same five day period and that it had failed to prevent the development of the diabetic tolerance curve even though it had finally halted the progressive rise of the fasting blood sugar level (Fig 1). Four days after cessation of

A C T H the curve indicated great improvement, and by the tenth post A C T H day recovery of carbohydrate tolerance was complete (Fig 2)

Subject D E, after five days of A C T H (Lot G 59703) showed a mild if significant, decrease in carbohydrate tolerance (Fig 4). On the seventh and eighth days of injection he received material from Lot 37 K G and the glycosuria increased abruptly along with a rise of the fasting blood sugar (Fig 3). Four days after cessation of A C T H, carbohydrate tolerance was still impaired but it was normal seven days later (Fig 4).

Fig 4—A C T H during the first six days was from Lot G 59703. During the last two days Lot 37 K G was employed.

Subject E S, chosen for this study because he had a pre-existing defect in uric acid metabolism (gout), reacted to A C T H in much the same way as did the normal subjects. Fig 6 shows that after twenty-four hours of A C T H (a total of 41 mg of Lot 37 K G) an intense loss of carbohydrate tolerance occurred. The initial control curve had been obtained two days previously. The next test done after two more days of injection of the same lot of A C T H indicated this subject's tendency to escape from the diabetogenic effect of the hormone. The glycosuria produced by Lot 37 K G disappeared entirely when Lot G 59703 was used (Fig 5). Normal tolerance for carbohydrate had returned by the sixth day following cessation of A C T H injections.

*Uric Acid Metabolism and the Level of Blood Glutathione*—The close relationship between increased urinary excretion of uric acid induced by

Fig 5—A C T H during the first three days was from Lot 37-K G During the last two days Lot G-59703 was employed

Fig 6—A C T H during the first three days was from Lot 37-K G During the last two days Lot G-59703 was employed

A C T H, and the development and persistence of glycosuria is observed again in this study (Figs. 1, 3, and 5) as it was in the previous one.<sup>1</sup> Note however, that the induction of glycosuria is related not only to increased production of uric acid but also to a concurrent fall of the level of blood glutathione, that the lower the glutathione in relation to a given level of heightened purine metabolism, the more intense is the glycosuria, and that a major difference between the highly diabetogenic preparation (Lot 37 K G) and less diabetogenic one lies in the capacity of the former to produce a sharper decrease in the level of blood glutathione. Subject D T (Fig. 3) demonstrates all three of these phenomena. With 26 mg per day of Lot G 59703, a rise in the excretion of uric acid occurred. This was not associated with a fall of the level of blood glutathione and glycosuria did not occur. When the dose of the same material was doubled a small amount of glycosuria occurred. Urinary uric acid did not change significantly but blood glutathione was mildly depressed. When 52 mg per day of Lot 37 K G were used blood glutathione fell precipitously and glycosuria increased sharply. There occurred too a mild increase of urinary uric acid. Upon discontinuation of A C T H a sharp rise of blood glutathione occurred.

Table II gives an index of the relative potencies of these two preparations of A C T H with respect to an effect unrelated to carbohydrate metabolism, namely, the increased excretion of 17 ketosteroids induced by the materials. Subject D T produced the same increase of 17 ketosteroids on 52 mg per day of Lot G 59703 as he did on 52 mg per day of Lot 37 K G. Yet the effect of the latter preparation on carbohydrate metabolism and upon blood glutathione (Fig. 3) was much more intense than that of the former.

The results of Subject H S (Fig. 1) leave no doubt that blood glutathione falls significantly in an individual who responds to A C T H with marked glycosuria. The administration of insulin did not prevent the fall of blood glutathione even though it was finally able to depress the level of the fasting blood sugar and to reduce the glycosuria. When on the last two days of A C T H the change was made from Lot 37 K G to Lot G 59703 glycosuria diminished even though no insulin was given. Blood glutathione rose. Urinary uric acid, urinary nitrogen, circulating eosinophiles and 17 ketosteroids (Table II) remained at levels which indicated continued activity of A C T H at least with respect to those indices. Thus it appeared that Lot 37 K G contained more of something which tended to depress blood glutathione than did Lot G 59703.

Subject E S (Fig. 5) demonstrated a small but definite fall of the level of blood glutathione. While Subjects R S and D E each showed a maximal fall of blood glutathione (below the average base line value) of 45 per cent that for E S was only 18 per cent. This may have been a factor in the ability of E S to recover tolerance for carbohydrate despite continued administration of Lot 37 K G (Fig. 6). It is interesting to note again that 52 mg per day of Lot G 59703 were roughly equivalent to 52 mg per day of Lot 37 K G in its ability to stimulate increased excretion of 17 ketosteroids (Table II).

† (Armour Standard)—Lot G-59703

and in its capacity to promote negative nitrogen balance (Fig 5). Mention should be made of the fact that A C T II produced no greater urinary excretion of uric acid in a patient with gout than it did in normal individuals.

*Protein Metabolism*—As noted previously<sup>1</sup> one finds again complete lack of correlation between protein metabolism and the occurrence of glycosuria. In Subject R S (Fig 1) negative nitrogen balance persisted for six days following cessation of A C T II, but glycosuria disappeared on the second post-injection day. Subject D E (Fig 3) developed no negative nitrogen balance as the result of A C T II. Nevertheless glycosuria appeared. It became evident first during a phase of nitrogen retention. This too has been noted before.<sup>1</sup> Subject E S (Fig 5) developed negative nitrogen balance and glycosuria under the influence of Lot 37 K G. When he was switched to Lot G 59703 negative nitrogen balance persisted but glycosuria disappeared promptly.

*Urinary Excretion of "Cortin" and of 17 Ketosteroids*—In the light of the metabolic changes presented it is of interest to examine in detail the results obtained from daily analyses of the urine for excretory steroids with particular reference to "cortin" (Table II). A great rise in the excretion of 17 ketosteroids was observed during the A C T II period in all three subjects. The maximal response observed for each subject was obtained and maintained with either preparation of A C T II administered at the same dose level. It is significant that regardless of which preparation had been maintaining the elevated excretion of 17 ketosteroids during the last two days of A C T II cessation of injections resulted during the next twenty-four hour period in a sharp fall of 17 ketosteroid excretion to levels approaching the base line values. This means that when excessive stimulation by A C T II of androgenic corticoid production ceases, excessive production of such steroids diminishes rapidly. It means, too, that urinary excretion of the metabolic end products (17 ketosteroids) is rapid in relation to the time of production of their precursors.

In contrast complete excretion of the cortin-like steroids appears to be characterized by a lag of about forty-eight hours after their production and after their physiologic effect has been observed. Subject D E (Table II) is seen to have shown his greatest rise of urinary "cortin" on the second day of injections of Lot 37 K G. A very high level of "cortin" excretion continued for two days after the injections were stopped. On the basis of these urinary values alone one might assume that time is required before the adrenal cortex responds to the stimulus, and that the cortex continues to produce excessive amounts of "cortin" for several days after the stimulus stops. A glance at Fig 3, however, is sufficient to destroy this interpretation. From a metabolic point of view, there is evidence of great increase of activity of "11-oxosteroids" only during the two days that Lot 37 K G was injected, and the most intense metabolic changes occurred during the first day of injection of this material (Day 7). During the first two recovery days (when "cortin" excretion was very high) all evidence of increased physiologic activity of cortin-like steroids had disappeared.

Similar interpretations cannot be made with equal assurance in the other two subjects because in them Lot 37 K G was given initially and they received

Lot G-59703 only during the last two days of injection (a time during which increased excretion of "cortin" would have been expected without injections, had they reacted similarly to Subject D E) Nevertheless, there is some evidence for existence of this same phenomenon In Subject E S (Table II) urinary "cortin" excretion reached its peak value during the fourth day of A C T H (three days of Lot 37-K G and one day of Lot G-59703) If urinary "cortin" were reflecting endogenous production of that material on the day of its excretion, one would expect the maximal metabolic effect to have been observed on the fourth day It is significant, however (Fig 5), that on the fourth day metabolic indices of "11-oxy steroid" activity had fallen sharply, particularly with reference to carbohydrate metabolism It seems most likely that the high urinary excretion of "cortin" on the fourth day of A C T H was due in part, at least, to excretion of metabolic end products of corticosteroids which had been produced earlier and which had exerted metabolic effects during the initial three days of injections The data on Subject R S (Table II and Fig 1) are not easily interpreted in this regard because this subject had received large amounts of insulin during the first six days of A C T H and none during the last two days That there existed excessive "11-oxy steroid" activity during the last two days of injections is obvious Whether it was as intense as during the preceding days is difficult to evaluate All things considered, the proposition seems justified that the metabolic end products of the 11 and 11-17 oxy steroids appear in the urine much later in relation to their time of production than do the excretory products of the androgenic corticosteroids

In connection with the variations in total nitrogen metabolism which are observed in different individuals exposed to the *same* adrenal cortical stimulus, it is of interest to examine the relative quantities of the two major types of excretory steroids which appear in the urine Subjects B S and E S developed negative nitrogen balance Total increases in both 17-ketosteroid and "cortin" excretion were of the same order of magnitude and proportionality Subject D E, who demonstrated no loss of body protein, showed much *lower* total excretions of 17-ketosteroids During the first six days of A C T H the proportionality of 17-ketosteroids to "cortin" was similar to that observed in the other two subjects But in the latter part of the A C T H period, when "cortin" excretion rose abruptly, unaccompanied by a rise of 17-ketosteroid excretion, no significant change in nitrogen equilibrium occurred (Fig 3 and Table II) It seems probable that over-all nitrogen balance depends upon the relative amounts of protein-anabolic and protein-catabolic steroids produced in response to an adrenal cortical stimulus but that the total quantity of "cortin" excreted gives no index of the amount of the protein catabolic steroid which contributed to the excretion of the total quantity of "11-oxy steroids"

#### DISCUSSION

Our previous report<sup>1</sup> and the present one indicate that glycosuria, increased levels of the fasting blood sugar, and glucose tolerance curves characteristic of the diabetic state can be produced in normal people by means of

the administration of suitable amounts of pituitary preparations, purified so as to contain mainly the adrenocorticotrophic hormone. It seems likely that in response to A C T H the elaboration of excessive amounts of certain of the adrenal corticosteroids (of the 11 and 11-17 oxygenated types) plays an important part in the initiation of the diabetic state. It is unlikely that the small amounts of *known* contaminants present in these preparations are capable per se of producing diabetes mellitus. Not ruled out are the possibilities (1) that one of these known contaminants potentiates the diabetogenic activity of the cortical steroids which are produced (2) that an unknown factor is present in the purified A C T H which increases the diabetogenic potentiality of excessive production of the so-called "S" type of corticosteroids or (3) that glycosuria is dependent upon excessive production of a specific 11 or 11-17 oxysteroid and that preparations of A C T H vary in their capacities to provoke increased production of that particular steroid. One of these possibilities is suggested by the experiments shown in Figs. 1, 3, and 5 in which Lot 37 K G was found to exert a much greater diabetogenic effect than Lot G 59703 when both preparations were alternated in the same three subjects. It seems significant too that in other respects the two preparations produced similar effects. In this connection it is evident that Lot 37 K G depressed the level of blood glutathione much more than did Lot G 59703. The possibility then that another factor is required in addition to increased "S hormone" activity in order that a marked diabetogenic effect be produced in the intact organism cannot yet be discarded. That there may exist more than one pituitary adrenocorticotrophic hormone must also be considered.

From the metabolic point of view the close association of impaired carbohydrate tolerance, increased uric acid excretion and depressed levels of blood glutathione is intriguing. The induction of alloxan diabetes in animals is associated with an abrupt fall of the blood glutathione to 50 per cent or more below the base line value.<sup>6</sup> Animals that resist the diabetogenic effect of alloxan show a much smaller, if any, depression of blood glutathione.<sup>6</sup> Suitable administration of large amounts of glutathione or of other sulfhydryl bearing compounds protects against the diabetogenic effect of alloxan.<sup>7</sup> Whether or not alloxan or other related compounds which selectively injure beta cells are normal intermediaries of purine metabolism they are chemically related to uric acid. Compounds of this family which are diabetogenic exert this effect only in the presence of a subnormal level of blood reduced glutathione. It has been reported recently by Griffith<sup>8</sup> that hyperglycemia can be produced in rabbits by intraperitoneal administration of uric acid providing that the level of blood glutathione is first lowered by means of a diet deficient in cystine and in methionine. These findings appear to be related to ours.

That an increased excretion of uric acid occurs in normal human beings given A C T H or adrenal corticosteroids of the 11 or 11-17 oxygenated types is now well known.<sup>9</sup> Whether the fall of blood glutathione which we have observed with A C T H is the result of an increased endogenous production of

alloxan or alloxan-like intermediaries associated with heightened purine metabolism (and thus an indirect effect of "11-oxy steroid" activity), or whether this fall is produced by an extraneous factor cannot be said at this time. In any case the data indicate (Fig 3) that in the presence of increased urinary excretion of uric acid a sharp fall of the level of blood glutathione is associated with an increase of glycosuria. Similarly, even in the presence of increased purine metabolism a rise of blood glutathione is associated with a decrease of glycosuria (Fig 1).

It is conceivable that in the presence of both lowered intracellular concentrations of reduced glutathione and heightened intracellular concentrations of purine metabolites, enzymatic production of insulin by the beta cell is impaired. This does not imply necrosis of beta cells, such as occurs following a large dose of alloxan during which the exposure of these cells is intense but transitory. In fact, the effective period after administration of alloxan is so transitory that exposure *must* be intense in order that any effect be demonstrable. However, when the cell is given a much smaller degree of the same qualitative exposure over a relatively prolonged period of time, it is logical to believe that the initially demonstrable abnormality will be functional rather than anatomical. It is probable, too, that the very function for which this cell exists (production of insulin) is the most important factor which makes it so selectively susceptible to the conditions mentioned. While this concept, with respect to production of a temporary diabetic state in normal human beings by means of the materials utilized in these experiments, is not firmly established it is believed that it constitutes a beginning which warrants further intensive investigation.

That there is involved, too, an extrapancreatic diabetogenic effect seems likely. In the experiment in which insulin was administered (Fig 1) the subject showed a greater resistance to insulin than is usually observed in a diabetic patient who exhibits a similar degree of reduction of carbohydrate tolerance. It could be argued that A C T H-induced diabetes is one which is based *entirely* upon a decreased effectiveness of endogenous insulin in the tissues and that the beta cells may be producing actually more than the normal quantity of insulin in response to "tissue requirements", that under these circumstances, fatigue of the beta cells will soon supervene, as evidenced by retrogressive cytologic changes and decreased secretory activity. It will be agreed, however, that if A C T H were still being administered at this time, resistance to exogenous insulin still would be evident. It is clear, then, that resistance to exogenous insulin gives no information relative to the total production of insulin by the pancreas. As judged by the amount of functioning pancreatic tissue which is needed in man, following partial pancreatectomy, to prevent the appearance of diabetes, A C T H-induced diabetes is compatible with a very significant decrease of the capacity of the beta cells to make insulin. It is to be recalled, too, that partially depancreatized animals, even though not diabetic, are much more susceptible to the diabetogenic effect of A P E (anterior pituitary extract) than are animals with pancreas intact.

The assumption that a decreased functional capacity of the beta cells occurs during A C T H administration (as a result of the metabolic aberration described) is easily reconcilable with the classical experimental results of Best,<sup>10</sup> Houssay,<sup>11</sup> and Lukens<sup>1</sup> and their respective associates. Best and co-workers<sup>10</sup> showed the existence of a *decreased content of pancreatic insulin* of dogs by the third day of A P E administration. On the basis of associated retrogressive changes in the beta cells it was concluded with justification, that the phenomenon was the result of extrapancreatic, hyperglycemic overstimulation of the beta cells. That this mechanism is an essential part of the evolution of beta cell degeneration goes without saying. Houssay and co-workers<sup>11</sup> observed a decreased *insulin producing capacity* of the pancreases of A P E treated dogs after three daily injections of the material but were unable to duplicate these findings in dogs given no A P E but given glucose in sufficient amount to maintain a hyperglycemia of the same degree and for as long as that observed in the A P E treated animals. It was shown too that as the functional reserve of the pancreas is diminished (by increasing degrees of partial pancreatectomy), increased sensitivity to the diabetogenic effect of A P E occurs. Dohan and Lukens<sup>1</sup> have demonstrated that hyperglycemia per se *if sufficiently intense and if sufficiently prolonged* is capable of inducing degenerative changes in the beta cells. The extreme resistance of normal beta cells to degeneration by means of hyperglycemia alone is noteworthy in their experiments. This is far different from the experience of all who have worked with A P E. In the latter case, both functional and retrogressive cytologic changes of the beta cells are demonstrable in three to four days during which time the hyperglycemia is much less intense than that which was found necessary in the glucose experiments of Dohan and Lukens. We suggest that the difference may be explainable on the basis of the increased vulnerability to hyperglycemia of beta cells which have been damaged functionally by the metabolic upheaval of purine and glutathione metabolism induced by A C T H.

Whatever may be the mechanism or combination of mechanisms which initiates impaired carbohydrate tolerance and hyperglycemia when purified A C T H is administered, it is reasonably certain that in highly responsive individuals such as Subject R S continued administration of the material would eventually result in permanent diabetes. Obviously, such an experiment is not justifiable. That there is great individual variation in the susceptibility of carbohydrate metabolism to injury by the measure used is clear. The variation may reside in differences in the capacities of normal individuals to maintain a reasonably normal level of reduced glutathione and of other sulfhydryl bearing compounds under the conditions imposed. This factor appears to be a determining one with respect to the diabetogenic potency of administered alloxan in animals. One could speculate that this factor may be involved in the well known familial susceptibility to diabetes mellitus.

A final comment is required concerning the changes in protein metabolism which were observed in the subjects of this investigation. Upon administration of A C T H the exhibition by a given subject of negative nitrogen

balance, nitrogen equilibrium, or positive nitrogen balance is dependent very likely upon the relative proportions of androgenic (protein anabolic) and of certain of the 11 and 11-17 oxygenated corticosteroids (protein catabolic or antianabolic) that are released in response to the stimulus<sup>4</sup>. But glycosuria occurred in all of our subjects regardless of the status of nitrogen metabolism. While glycosuria and loss of carbohydrate tolerance are more intense in those who demonstrate negative nitrogen balance, the latter is not a necessary accompaniment. It is believed that the emphasis, rather than being upon excessive glycconeogenesis from protein, should be upon the fact that A C T H causes an over-all reduction of the capacity of the body to utilize normally those elements which enter into the "carbohydrate pool," regardless of their source. Loss of body protein and decreased carbohydrate tolerance are metabolic effects probably produced via the same types of corticosteroids. In different individuals, however, these effects may vary independently of each other indicating (1) that each is not dependent for its existence upon the other and (2) that such variations may be manifestations of individual differences in end organ responses to similar stimuli, or manifestations of individual differences in the production of specific steroids belonging to the 11 and 11-17-oxy steroid family.

#### SUMMARY

A state of metabolism similar in all respects to clinical diabetes mellitus has been produced in normal human beings by the administration of a purified preparation of adrenocorticotrophic hormone. It seems evident from the results that permanent diabetes mellitus in man could be produced with this material were caution not exercised with respect to duration of administration and dosage employed. The diabetes evidenced during such treatment was found to be relatively resistant to exogenous insulin. This fact does not indicate necessarily that resistance to endogenous insulin is the mechanism by which loss of carbohydrate tolerance is affected by A C T H.

Analysis of the metabolic data discloses a consistent correlation between loss of tolerance for carbohydrate, increased endogenous purine metabolism, and depressed levels of blood glutathione. It is suggested that A C T H may affect changes in the composition of intracellular fluid which include (1) increased concentrations of intermediaries of purine metabolism and (2) decreased concentrations of sulfhydryl bearing compounds. It is suggested, further, that since the beta cells of the islets of Langerhans are known to be more sensitive to injury by the aforementioned intracellular alterations (probably by virtue of their insulin-producing function) than are any other cells of the body, a functional impairment of these cells occurs which increases their vulnerability to hyperglycemia.

Negative nitrogen balance is not a necessary accompaniment of glycosuria produced by A C T H. Although greater loss of carbohydrate tolerance is observed in subjects who lose body protein, the two metabolic phenomena are not mutually dependent. Specific steroids of the 11 or 11-17 oxygenated types may be responsible for each phenomenon.

Some of the data suggest that there may exist more than one pituitary adrenocorticotrophic hormone

# INTENTIONAL ISOIMMUNIZATIONS AGAINST THE ANTIGEN D (Rh<sub>0</sub>)

ROBERT K. WALLER, M Sc  
RICHMOND, VA

WITH THE TECHNICAL ASSISTANCE OF MARION WALLER, B A

NATURALLY occurring anti-Rh antibodies either do not exist or are exceedingly rare. Those produced by isoimmunization in pregnancy are frequently of low titer and many times contain a mixture of antibodies, all factors making them an unreliable and sometimes undesirable source of this highly sought after laboratory reagent.

With the report by Hill, Haberman and Orozco<sup>1</sup> on preparation of anti-Rh sera by injection of Rh-positive cells into previously immunized Rh-negative women, a method became available to increase the supply of this valuable reagent\*. Previously it had been shown that experimental sera produced in various animals not only have the disadvantage of small quantity and low titer but exhibit a certain lack of specificity, particularly when tested against cord cells or cells from newborn infants.

The next important contribution toward production of specific and potent sera was made by Wiener and Gordon<sup>2</sup> who carried out intentional immunizations of normal Rh-negative men by injection of Rh-positive cells of a known specificity. Their injection schedule called for two intravenous injections of 4 c.c. each of a 50 per cent red cell suspension at four-month intervals, followed by bleeding of the donors approximately ten days after the last injection. By this method they sensitized five of nine individuals but obtained only two sera sufficiently potent for laboratory purposes. In an addendum they report a yield of five useful sera from six injected individuals immunized over a period of one year with injections at six-week intervals.

While the studies described below were in progress, Van Loghem<sup>3</sup> reported the production of anti-C (1h') and anti-E (1h'') sera by means of artificial immunization of volunteer donors.

The purposes of our investigation were to determine the types of antibodies produced as well as the order of their appearance, the incidence of individuals who could be immunized by the method used, and the minimum quantity of red blood cells required to produce immunization. An additional important consideration was our endeavor to obtain a supply of potent anti-Rh serum.

## METHOD

Ten white Rh negative volunteers who had never received transfusions or intramuscular injections of blood as far as could be ascertained were selected for this experiment. Each of them received an initial intravenous injection of a 50 per cent cell suspension of the type

From the Department of Clinical Pathology, Medical College of Virginia.

Aided by a grant from the Virginia Academy of Sciences.

Received for publication Oct. 24, 1948.

\*At the International Hematological and Rh Conference (Dallas, Texas, 1946) L. Diamond reported unpublished experiments with intentional immunizations dating back to 1942. By 1946 he had treated over sixty-five subjects with 75 per cent success.

O Dec (Rh)<sup>+</sup> On the basis of a 47 per cent hematocrit this was calculated to contain approximately 117 cc of packed cells. All subsequent injections were administered at six week intervals and group O type  $\frac{DcF}{DcE}$  (Rh homozygous) cells were used for these and all other injections. Each dose comprised a packed cell volume of 1 cubic centimeter. Before the initial injection and at the time of each subsequent injection, sera were obtained from all ten individuals and tested for the presence of antibodies by means of the saline agglutination technique, the 20 per cent bovine albumin, and the Coombs antihuman precipitin technique,<sup>4</sup> using the injected cells and a cell of the type DCE as antigens. As soon as any sensitization could be detected the injection schedule for the particular individual was changed to ten day intervals in order to speed up the process of antibody formation. All sera containing antibodies were tested for their specificity with appropriate cells.

## RESULTS

The first antibody response occurred simultaneously in three individuals after the third injection. The cell volume injected up to that time comprised a total of 317 cc each. After the fourth injection, four subjects responded with antibody formation, and after the fifth and sixth injections seven and nine

TABLE I

NUMBER OF IMMUNEFESPONSES	NUMBER OF INJECTIONS	APPROXIMATE CELL VOLUME INJECTED (CC)
0	1	117
0	2	217
3	3	317
4	4	417
7	5	517
9	6	617

sensitizations respectively could be detected. The maximum total volume of cells injected into any one volunteer was 617 cubic centimeters. These results are summarized in Table I.

As shown in Table II, the three individuals who produced antibodies after only three injections responded with formation of saline agglutinins to a titer of about 1:10. The reactions obtained in 20 per cent bovine albumin were found

TABLE II

SUBJECT	TITER		
	SALINE AGGLUTINATION	20 PER CENT BOVINE ALBUMIN	COOMBS REAGENT

Bu	10	10	160
Me	<10	<10	<10

to be within approximately the same range, whereas the Coombs reagent in two out of the three sera demonstrated antibody titers which far exceeded those obtained by either the saline or albumin techniques.

All four subjects who required only three or four stimulations produced initially saline agglutinins which in the course of further injections showed a

This suspension was prepared by withdrawing 30 ml of venous blood from the donor and mixing it with an equal amount of 3.6 per cent sodium citrate in a sterile bottle. The resulting suspension was thoroughly mixed by shaking and 5 ml were used for each injection.

definitive rise and fall in titer, even to a level of complete disappearance.\* At the same time the reactions elicited in 20 per cent bovine albumin media increased in titer consistently. The titer of antibodies detected by means of the Coombs technique exceeded the titers in bovine albumin in two of the four cases whereas identical results were observed in the other two. The above-mentioned titration difference amounted to between three and four double dilutions. Typical samples of these findings are shown in Table III.

TABLE III

NUMBER OF INJECTIONS	TITFP

4	8	128	512	32	32	32
5	256	256	1024	256	256	256
6	16	256	2048	0	512	512

The remaining five cases which required five or more injections for production of antibodies failed to show saline agglutinins. The titration values in bovine albumin and those obtained with the Coombs reagent ranged from 1/2 to 1/64, but in no case did the Coombs technique detect antibodies of significantly greater strength than those demonstrated in albumin media. One subject (C B) who responded after the fifth injection was found to have lost all detectable antibodies after a subsequent injection. Because the original titer was low these results were seriously questioned, but on re-examination of the old specimen

preserved at icebox temperature the antibodies found previously could still be detected. One of the ten cases failed altogether to show any antibody response after six administrations of six-weekly injections amounting to approximately 6 c.c. of packed cells. Typical examples of the late immune response are shown in Table IV.

Three of the donors having sera with maximum titers of 2048, 512, and 64 respectively were retested eight weeks after their last injection. None showed

\*The same observation was made by Levine and Wigod in cases of isoimmunization in pregnancy. (Personal communication)

diminution in titer or qualitative change in antibodies. The same sera were again retitrated after six months of storage at +7° C and the results were identical or within one double dilution which is considered to be within the limits of the experimental error.

With reference to the specificity of the antibodies produced in the nine volunteers, eight were found to correspond completely to anti D (Rh<sub>0</sub>). One individual (Mr.), however, was found to have produced anti C (rh') and anti D (Rh<sub>0</sub>) antibodies of equal titer and quality. Because of this unexpected result the serum was submitted to Dr. Philip Levine who was able to confirm our observation. Consequently, because it was suspected that the cells used for our immunization were actually Dce (Rh<sub>1</sub>) and not Dce (Rh<sub>0</sub>) or DeE (Rh<sub>1</sub>), they were subjected to a battery of anti C sera in our laboratory as well as in Dr. Levine's. All tests failed to disclose the presence of a C antigen. Because of the experience of Van Loghem, who by injection of cells presumably of type dCe (rh<sub>1</sub>), but actually D Ce obtained in anti D + C (Rh'<sub>0</sub>) serum, the cells used in our experiments were submitted to Dr. R. R. Race in London for detection of an intermediate C antigen. Dr. Race reported the absence of C, C<sup>u</sup>, C<sup>w</sup> or c<sup>w</sup>, thus leading us to believe that the volunteer must necessarily have received other Rh positive blood at a previous occasion. Further search into his history by close questioning and conference with his mother failed to reveal any previous incidence of intravenous or intramuscular injection of blood. It is of interest to note that this same individual was the only one who reported a reaction\* after every injection including the first one and was the only one who during the series of injections developed infectious hepatitis.

#### DISCUSSION AND SUMMARY

With the method presented, it was possible to immunize nine of ten human subjects using six intravenous injections to a total of about 6 ml of cells. Five of the individual sera produced were sufficiently potent to be used as laboratory reagents.

The immune response between those who required only three or four injections and those requiring more seemed to differ significantly. The absence of saline agglutinins in the late immunizations is rather striking. As observed in some sera there was a marked difference between reactions obtained in albumin media and those obtained with the Coombs reagent. Although it is well known that this reagent is more sensitive than any other method used for the detection of sensitization, it is difficult to understand why this difference in titer should appear only in some sera and not in all. One possible explanation may be the presence of a third order antibody as previously postulated by Hill and Harberman<sup>5</sup>. It is of interest to note that this discrepancy in titer was observed only in those volunteers who were immunized with relative ease.

As regards the stability of the antibodies produced they were found to be at least as stable as or more stable than those occurring in cases of isoimmunization in pregnancy.

\* Pain in eyeballs and lumbar region, slight elevation of temperature and chills

The disappearance of antibodies after a subsequent injection of the antigen, as occurred in one case, is compatible with the phenomenon of negative phase of immunization which was recently observed to occur even during natural immunizations against Rh<sup>6</sup>

The presence of anti-C in addition to anti-D in the serum Ma cannot be explained satisfactorily. Although nonspecific antibody production is known to occur, as for instance described for the M and N system by Landsteiner and Levine,<sup>7</sup> this is usually observed in low titers. The fact that the nonspecific antibody observed in our case was of high titer and equal to the specific one makes this explanation less likely. In attempting to explain the phenomenon observed, the following possibilities should be kept in mind. First, the history may have been incorrect and our volunteer possibly received an injection of foreign blood as a child. This appears most likely because of the reaction reported by him even after the first injection. Second, it is remotely possible that the cells used for injection contained a hitherto undetected variation of the antigen C, capable of producing anti-C antibodies. Third, one should consider that other antigenic stimuli, even the attack of homologous serum hepatitis, may have been responsible for the nonspecific antibodies observed.

In comparing the minimum amounts of cells necessary to produce immunization against C (1h') and E (1h'') in the series of Van Loghem<sup>3</sup> and those found necessary in our experiments, the following results can be obtained (Table V)

TABLE V

ANTIGEN INJECTED	D	C	E
Minimum amount of cells necessary to immunize (c c)	3 17	6 5	13 0

From these findings it appears that with the decrease in antigenicity of the cells the quantity of antigen must be doubled. Whether these results are significant or accidental can be established only by a larger series.

## LABORATORY METHODS

### DETERMINATION OF PHENOL IN BIOLOGIC MATERIAL

G GOMORI M D PH D

CHICAGO ILL

THERE are a number of color reactions for phenol available some of which lend themselves readily for the determination of phenolic substances in biologic material. Tests for phenol were reviewed by Gibbs<sup>1</sup> in 1926 and their applications to biology by Deichmann and Schaefer in 1942.

For biologic uses the most commonly employed methods are the molybdenum blue method of John and Cioculieu<sup>2</sup> and the azo dye method introduced by Theis and Benedict.<sup>3</sup> The latter method is distinctly preferable because of its far greater sensitivity and specificity. Its main disadvantage is the lability of the diazo reagent which must be prepared fresh daily. To obviate this disadvantage it was attempted to utilize one of the commercially available stabilized diazo salts which under suitable conditions have good keeping properties. Fifteen such compounds were tested and, although several of them proved to be usable diazotized 5 nitro 2 aminoanisole\* was selected as the reagent of choice because of the intense orange red shade it gives on coupling with phenol. This shade is quite stable in the presence of 4 to 6 per cent alcohol whereas in a purely aqueous medium it gradually fades. Alcohol in concentrations in excess of 7 per cent inhibits full development of color. With phenolic substances other than phenol itself the optimal concentration of alcohol may be higher or lower also the shade and intensity of the color of the azo dye may be different. Certain substances such as salicylic acid and p substituted phenols give pale shades. Table I shows the molar efficiency (i.e., the ratio of

molar concentration of phenol
molar concentration of substance in question

giving the same colorimetric readings) of the method in the case of various phenolic substances. In addition a number of nonphenolic compounds considered likely to give color are also listed.

As shown, the molar efficiency for substances of nonphenolic nature is so low as to rule them out as sources of error

#### METHOD

*Reagents*—1 Saturated solution of borax in 15 per cent alcohol To 1,000 ml of 15 per cent alcohol add about 35 Gm of powdered borax ( $\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$ ) and shake repeatedly Some of the borax will remain undissolved This reagent is stable

2 Diazo reagent Dissolve 0.25 Gm of Red B Salt (or any of the other brands mentioned) in 100 ml of ice cold water and filter Add 1 ml of 5 per cent  $\text{H}_2\text{SO}_4$  This solution will keep in the ice box for over two weeks

*Standardization of Curve*—Prepare a stock solution of phenol (reagent grade, purity  $\pm 99$  per cent) containing 1 mg of phenol in 10 milliliters Make a series of dilutions by pipetting 0.5, 1, 2, 3, and 5 ml of the stock solution into 100 ml volumetric flasks and filling them up to the mark with water Measure 5 ml samples of each (covering the range of 2.5 to 25  $\mu\text{g}$  of phenol per sample) into colorimetric test tubes, use the same amount of water as a blank Add to each tube 1 ml of water and 4 ml of borax solution Invert tubes twice Add 0.5 ml of diazo reagent Invert tubes twice Read between three and sixty minutes after mixing, using a 490  $\text{m}\mu$  (blue green) filter Plot data on semilogarithmic graph paper A straight line should be obtained

*Determination of Phenol in Unknown*—Unknown (urine, serum, and so forth), 1 ml, water, 5 ml, borax solution, 4 ml, diazo reagent, 0.5 milliliter Read against blank as before In case the specimen is not colorless, two blanks must be used A, specimen replaced by water, B, diazo reagent replaced by water Both unknown and the blanks are read against pure water, and the sum of values for A and B is deducted from the value for the unknown If, owing to large amounts of phenol present, the shade is too dark for reading, both unknown and blank are diluted to a convenient larger volume (e.g., 25 or 50 ml) with 4 per cent alcohol, and the values are multiplied by a corresponding factor The amount of diazo reagent given is sufficient up to 120  $\mu\text{g}$  of phenol For special purposes, the technique may be modified For instance, in the case of a Folin Wu filtrate, take a 5 ml sample, add 1 ml of 0.3N NaOH (to neutralize the acid), 4 ml of borax, and 0.5 ml of diazo reagent

#### RESULTS

The present method was used for the determination of phenol in serum (ten cases), in Folin-Wu filtrates of serum (five cases), in histamine-stimulated gastric juice (191 cases), and in urine (forty-nine cases) The readings on serum were invariably higher (range, 17 to 32  $\mu\text{g}/\text{ml}$ ) than in the corresponding Folin-Wu filtrates (range, 7 to 10.4  $\mu\text{g}/\text{ml}$ ) because phenolic groups in

proteins also react. The range in gastric juice was 1.4 to 56  $\mu\text{g/ml}$ , in urine, 0.9 to 44  $\mu\text{g/ml}$ . All urines containing more than 25  $\mu\text{g}$  of phenol were positive with Ehrlich's diazo reaction.

#### OTHER APPLICATIONS OF THE PHENOL REACTION

The reaction described can be used for the determination of phosphatase activity, both in the acid and alkaline range with the advantage that the step of deproteinization becomes unnecessary. The introduction of a new substrate (phenyl benzoate) permits the determination of lipase (esterase) activity in a highly accurate, simple and inexpensive way.

TABLE II EFFECT OF BORATE ON HYDROLYSIS OF PHOSPHORIC ESTERS

(Enzyme Solution of purified extract of *log* intestine 1:500 dilution, 1 ml 0.005M in 0.05M buffer of pH 9.2 Mg 0.005M Activity expressed in  $\mu\text{g}$  of P liberated in 1 hour Temp, 37°C)

SUBSTRATE	ACIDITIAL BUFFER	BORATE BUFFER
Glycerophosphate	102	57
Phenylphosphate	93	96

**Phosphatases**—The substrate is King and Armstrong's<sup>5</sup> diNa phenyl phosphate. The buffer in the acid range is acetate while in the alkaline range it is borate. The latter is a cheap and efficient buffer at the optimum range of alkaline phosphatase in case of phenylphosphate as a substrate (around pH 9.8).<sup>6</sup> In preliminary experiments it was shown that borate does not inhibit the hydrolysis of phenylphosphate while it strongly inhibits that of glycerophosphate (Table II).

**Reagents**—1. Substrate diNa phenylphosphate approximately 0.05M. Use a good grade chemical, low in phenol or, if such is not available extract about 1.1 Gm of diNa phenylphosphate with about 100 ml of hot alcohol, dry and dissolve it in 100 ml of distilled water.

2. Acetate buffer, 0.05M, pH 5. Dissolve 4.75 Gm of Na acetate and 0.9 ml of acetic acid in 1,000 ml of water.

3. Borate buffer, 0.1M, pH 9.2 to 9.8. Dissolve 9.5 Gm of borax and 30 to 35 ml of 4 per cent NaOH in 1,000 ml of water.

4. Twenty per cent solution of magnesium chloride.

**Determination of phosphatase activity** A, Alkaline phosphatase. Buffered substrate (borate buffer, 90 ml; substrate 10 ml; Mg solution, 1 ml; mixture will keep in the refrigerator for several months), 5 ml; serum dilution 1:25 (1 milliliter Blank buffered substrate without serum). Incubate tubes at 37°C for one hour. Place tubes in ice cold water. Add to blank 1 ml of serum dilution. Determine phenol as described.

B. Acid phosphatase. Buffered substrate acetate buffer, 90 ml; substrate 10 milliliters. This mixture will undergo slow hydrolysis even in the refrigerator and should not be kept for longer than two weeks. Procedure otherwise is identical with the previous one.

There are a number of arbitrary units of phosphatase activity described in literature four of which are being widely used (Bodansky,<sup>7</sup> King Armstrong,<sup>8</sup> Huggins and Talalay's<sup>9</sup> phenolphthalein, and Bessey and co workers<sup>10</sup> nitrophenol units). It is suggested in order to facilitate direct comparison of results obtained with various methods that the activities of all hydrolytic enzymes be expressed in terms of micromoles of ester linkages split in one hour by 1 ml (or 1 Gm) of biologic material preferably under optimal conditions or in some cases under the special conditions of the experiment re-

gardless of the compound actually determined colorimetrically or by any other means, and regardless of the actual length of time of incubation Table III gives a comparison between the various units of alkaline phosphatase activity, the determinations having been performed with human serum exactly according to the authors' specifications. It should be remarked, however, that neither the Bodansky nor the King-Armstrong technique utilizes optimal conditions. Both omit the addition of Mg, and for this reason the Mg concentration is suboptimal ( $10^{-4}$  M or less, instead of  $10^{-3}$  to  $10^{-2}$  M), moreover, in the

TABLE III EQUIVALENTS OF UNITS OF ALKALINE PHOSPHATASE ACTIVITY

UNIT	DEFINITION	EQUIVALENTS
Bodansky	1 mg of P/h/100 ml	1.24
King-Armstrong	1 mg of phenol/30 min /100 ml	2.60
Nitrophenol	1 mM of nitrophenol/h/1,000 ml	0.69
New method	1 $\mu$ M of phenol/h/ml	1

case of the latter one, the pH of the buffered substrate is below the optimum (9.3 to 9.35 instead of 9.8). The ratios may be significantly different in the case of alkaline phosphatases other than that of human serum (unpublished data). No direct comparison between the phenolphthalein unit and the other units is possible because the relationship between the amount of phenolphthalein liberated and the amount of enzyme is not rectilinear.

The phosphatase activities of fifty-one unselected human sera were determined by the new method. The range of normal values at alkaline pH was from 2.3 to 6.6  $\mu$ M/milliliter. Four sera from patients with obstructive jaundice read 9.2, 12.6, 13.4, and 16.2  $\mu$ M/milliliter respectively. The range of values at acid pH was from 0.64 to 1.48  $\mu$ M/milliliter.

*Esterase (Lipase)*—Techniques utilizing the Warburg apparatus are obviously not suitable for the purposes of a clinical laboratory, those based on titration of acid liberated<sup>10, 11</sup> are not sensitive enough, the results of the stalagmometric method<sup>12</sup> do not lend themselves to a strict quantitative evaluation. The first colorimetric method sufficiently sensitive and simple to be used in the clinical laboratory is the p-nitrophenol ester method of Huggins and Lapides.<sup>13</sup> Its disadvantage is the lability of the substrate, necessitating the frequent preparation of fresh solutions and the running of the test at a nonoptimal pH.

The method to be described utilizes phenyl benzoate as a substrate. This ester is crystalline, available practically phenol-free,\* and fairly stable both in alcoholic and aqueous solutions. Fatty acid esters (acetate, propionate and butyrate) of phenol were found to contain significant amounts of free phenol which it was impossible to remove. Phenyl benzoate is only very slightly soluble in water (about 40 mg./l. at 23° C.) but as will be shown, the saturated solution is entirely satisfactory for the measurement of esterase activity within wide limits.

Phenyl benzoate is readily hydrolyzed by both lipase and esterase as shown in Table IV. The rates of hydrolysis of methyl butyrate and of Tween 20 were determined by the following adaptations of the author's methods for choline

\*Eastman No. 632

esterases<sup>14</sup> there was a replacement of substrates (methyl butyrate, 0.01 M Tween 20, 0.25 per cent), in addition, instead of using prostigmine, enzymatic activity was stopped by immersing the tubes in ice cold water. To the blanks the enzyme was added just before titration or turbidimetric reading. Gelatin was omitted from the CaCl<sub>2</sub> solution because it caused a turbidity with Tween 20. Hydrolysis of olive oil was determined by titration in 80 per cent alcohol.

TABLE IV RATES OF HYDROLYSIS OF VARIOUS SUBSTRATES BY LIPASE AND LESTASE  
(Enzymes: 1:10 homogenates of guinea pig pancreas and liver and human serum. Activities expressed in  $\mu$ M of acid liberated by 1 ml in 1 hour)

SUBSTRATE	LESTASE (LIVER)	LIPASE (PANCREAS)	SERUM
Olive oil	None	165	None
Tween 20	46	116	8
Methyl butyrate	600	190	45
Phenyl benzoate	440	126	41

The dependence of the rate of hydrolysis on pH is shown in Table V. The optimum is between 6.0 and 6.5 which value is considerably lower than in the case of most other substrates (around pH 8).

TABLE V EFFECT OF pH ON RATE OF HYDROLYSIS OF PHENYL BENZOATE BY PANCREATIC LIPASE  
(Enzyme: Armour's pancreas powder 1% suspension diluted 1:50. Buffer: tris(hydroxy methyl) aminomethane maleate<sup>15</sup>)

pH	5.0	5.5	6.0	6.5	7.0	7.5	8.0
$\mu$ g of phenol/h	11	13.5	15.5	15	13	8.5	5.3

Hydrolysis is proportional to time for at least two hours provided not more than 30 per cent of the substrate (equivalent to 28  $\mu$ g of phenol in 2.5 ml sample) is used up (Table VI).

TABLE VI COURSE OF HYDROLYSIS IN TIME  
(Enzyme: human serum diluted 1:150)

TIME (MIN)	10	20	30	40	50	60	80	120
$\mu$ g of phenol	1.9	3.9	6.0	7.8	9.7	11.6	17.4	22.5

Provided not more than 30 per cent of the substrate is split in the course of the experiment, there is a linear relationship *within wide limits* between the amount of enzyme and the rate of hydrolysis (Table VII).

TABLE VII EFFECT OF ENZYME CONCENTRATIONS  
(Enzyme: as in Table V)

1 Enzyme dilution	500	250	100	100	50	25	20	16	13	10
2 Relative amounts of enzyme	2	4	5	10	20	40	50	63	75	100
3 $\mu$ g of phenol/h	0.6	1.8	2.2	4.3	8.4	16.6	21.2	25.4	29.4	31.5
4 $\mu$ g of phenol/relative amounts of enzyme	0.30	0.45	0.44	0.43	0.42	0.41	0.42	0.40	0.39	0.32

## METHOD

*Reagents*—1 Phenyl benzoate stock solution Dissolve 2 Gm of phenyl benzoate in 100 ml of methanol This solution will keep in the refrigerator indefinitely

2 Phosphate buffer, 0.1 M, pH 6.3 Dissolve 5.35 Gm of  $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$  and 7.0 Gm of  $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$  in 1,000 ml of water

3 Buffered substrate into 500 ml of buffer blow 1 ml of substrate stock solution Stir Keep in the ice box The buffered substrate will undergo very slow hydrolysis, producing slightly colored blanks, but will remain usable for about two weeks Shake before use because some of the ester will precipitate in the cold

*Determination of esterase activity*—To 5 ml of prewarmed buffered substrate add 1 ml of enzyme (serum dilution 1:200, gastric juice 1:25, and so on) Procedure is otherwise identical with that for phosphatases

## RESULTS

The esterase activity of fifty-one human sera and of 242 gastric juices was determined The range in the sera was between 14.5 and 41.2  $\mu\text{M}/\text{milliliter}$  in forty-eight cases out of fifty-one Three cases had activities of 52, 47.5, and 54  $\mu\text{M}/\text{milliliter}$ , respectively The first two were cases of diabetes, and the third one was a psychiatric case In three cases parallel determinations of serum esterase activity by Huggins and Lapidès' p-nitrophenol propionate (PNPP) method and the new method were done It was found that 1 PNPP unit was equal to 0.3  $\mu\text{M}/\text{milliliter}$  according to the new method

The range of concentration of enzyme in gastric juices corresponded to 1.2 and 200  $\mu\text{M}/\text{milliliter}$ , 220 out of 242 cases having an activity lower than 40  $\mu\text{M}$  Gastric juices containing gross bile were especially numerous among cases with very high activities, indicating regurgitated intestinal and pancreatic juice as the possible source of the excess enzyme On the other hand, many juices containing gross bile showed low activities Table VIII shows the statistical distribution of esterase activity in gastric juices

TABLE VIII DISTRIBUTION OF ESTERASE ACTIVITY IN GASTRIC JUICES (242 CASES)

RANGE ( $\mu\text{M}/\text{ml}$ )	1-2.5	5-10	10-20	20-30	30-40	40-50	50-70	70-100	OVER 100
Number of cases	7	57	101	40	14	2	3	8	10
Gross bile	2	17	18	6	4	None	1	6	6

There is a marked irregularity in the shape of the frequency distribution curve between 30 and 70 micromoles For this reason, the cases showing activities over 70  $\mu\text{M}$  were analyzed separately in respect to diagnosis Nine patients had no demonstrable gastric lesions, five of them had normal acid values, and four were anacid Of the remaining nine, two had carcinoma of the stomach, six had duodenal ulcers treated by x-ray irradiation (five anacid, one normacid), and in one the diagnosis was atrophic gastritis with achlorhydria As far as the relationship between acid values in general and esterase

activity is concerned, Fig 1 shows a scattergram of eighty two cases selected at random from all ranges of acidity and esterase activity. Except for the fact that very high activities are almost invariably associated with low acid values or with anacidity, there is no apparent correlation between acidity and esterase activity of gastric juice.

Fig 1—Relationship between free acid values and esterase activity

#### SUMMARY

A new and simple azo dye method for the determination of phenol phosphatases, and esterase in biologic material is described. Range of phosphatase and esterase values as determined with the new method is given.

# A SIMPLE METHOD FOR THE DETERMINATION OF FECAL FAT AND FATTY ACIDS

JOSEPH L. ZUCKERMAN, MICHAEL C. ZIMARIS, B.S., AND  
SAMUEL NATELSON, PH.D.  
BROOKLYN, N. Y.

**I**N CLINICAL diagnosis of sprue,<sup>1</sup> celiac syndrome,<sup>2</sup> and cystic fibrosis, fecal fat determinations are often of value. The most commonly used methods are those of Kaye<sup>3</sup> and Tidwell and Holt.<sup>4</sup> The Tidwell and Holt method is time consuming, requiring 200 ml. of solvent which must be evaporated to dryness on a steam bath. The Kaye method is even more tedious and requires eleven hours of extraction.

In the new method which we present here a result may be obtained within two and one-half hours after the stool is dry. This procedure is particularly applicable to routine hospital determinations in that forty determinations may easily be carried out in one working day.

We have found that stool may be dried to constant weight at 60° C. overnight. An advantage of drying at 60° C. is that no objectionable odors are evolved. At 100° C. some pyrolysis takes place as indicated by the acrid odors given off. Drying at 60° C. may therefore be done in an electric oven without the use of a hood. By homogenizing the stool and taking approximately a 2 Gm. sample which is spread on the bottom of a 50 ml. beaker or Petri dish, approximately forty samples may be dried in a standard electric incubator at one time. Where the original sample is small, as for infants, the stool is collected in shallow, wide-mouth jars which are placed directly in the 60° oven.

The dried stool is pulverized and samples are weighed into test tubes. To the test tube is added dilute HCl to free the fatty acids from the soaps and a petroleum ether-diethyl ether mixture to extract the lipids. One drop of ethyl alcohol is also added. This serves to prevent the mixture from emulsifying when shaken. The extraction is now accomplished by shaking in a standard shaking machine on which has been mounted a special carrier designed to accommodate large numbers of tubes. This carrier has been previously described.<sup>5</sup> The tubes are then centrifuged and the ether mixture is aspirated off. This process is repeated. The combined extracts are evaporated to dryness and weighed. Studies have shown that by these two extractions 98 to 99 per cent of the fat is extracted. Further extractions are therefore unnecessary for routine determinations.

If free fatty acid determinations are desired, alcohol is added to the extracted lipid and the solution is titrated with alkali. Thus by this method both total fat and fatty acids may be determined at the same time. Recoveries

Received for publication Sept. 27, 1948.

were made up by dissolving one part of stearic acid in two parts of molten lard, 185 mg of this mixture were added to 500 mg of dried stool. Table I summarizes the results of ten such recoveries.

TABLE I RECOVERY OF FAT AND FATTY ACID ADDED TO TEN SAMPLES OF DRIED STOOL

A	WEIGHT OF DRIED STOOL SAMPLE (MG)	WEIGHT OF TOTAL FAT EXTRACTED (MG)	FAT ADDED (MG)	FAT RECOVERED (MEAN) (MG)	AVERAGE DEVIATION FROM MEAN (%)
	500	133	185	185	±0.40
B	MEAN TITRATION OF FAT EXTRACTED FROM STOOL (0.1N NaOH)	MEAN TITRATION OF FAT ADDED (185 MG)	MEAN TITRATION OF FAT RECOVERED	AVERAGE DEVIATION FROM MEAN TITRATION	
	2.49 ml	1.79 ml	1.78 ml	±0.03 ml	

Table II shows typical results obtained in normal adults and children.

TABLE II PER CENT FAT IN STOOLS OF NORMAL ADULTS AND CHILDREN

CASE	AGE (YR)	WEIGHT OF FAT RECOVERED FROM 500 MG OF STOOL (MG)	PER CENT FAT IN DRY STOOL	CASE	AGE (YR)	WEIGHT OF FAT RECOVERED FROM 500 MG OF STOOL (MG)	PER CENT FAT IN DRY STOOL
1	2	48	9.6	10	5	99	19.8

9	45	32	6.4	18	25	33	6.6

## REAGENTS

1 *Hydrochloric Acid (1N)*—Made up by diluting the concentrated acid (12N) to twelve times its volume with water.

2 *Petroleum Ether Ether Mixture 1:1*—Made by mixing equal quantities of redistilled petroleum ether (boiling point 70 to 90°) and redistilled diethyl ether.

3 *Ethyl Alcohol 95 Per Cent (Redistilled)*

4 *Sodium Hydroxide 0.1N*—This must be standardized daily against 0.1N standard sulfuric acid.

5 *Standard Fat for Recovery*—To 8 Gm of lard melted at 100° C were added 4 Gm of stearic acid. The mix was stirred until homogeneous and allowed to cool. The solid fatty mixture was dissolved in benzene and dried over CaCl<sub>2</sub> overnight. The CaCl<sub>2</sub> was filtered off and the benzene was evaporated off under vacuum. The residue was brought to constant weight in a vacuum desiccator.

## PROCEDURE

The total stool or approximately 2 Gm of the homogenized stool are dried in a beaker by placing it in an electric oven at 60° C overnight. Duplicate 500 mg samples are weighed into clean, dry 15 ml test tubes with either ground glass or Tygon stoppers. To each tube is added the following

5 ml 1N HCl

5 ml petroleum ether-ether mixture

1 drop 95 per cent ethyl alcohol

The tubes are carefully stoppered and shaken for twenty-five minutes in a shaking machine.

The Tygon stoppers are constructed by sealing both ends of a short piece of glass tubing (8 mm outside diameter, 1.5 cm in length). The sealed tube is inserted into a piece of Tygon tubing (outside diameter 1.5 cm, length 1.7 cm). These stoppers are then extracted with petroleum ether to remove any possibility of fatty materials being present. This should be repeated each time the stoppers are used.

After the tubes have been shaken, they are centrifuged at 2,500 revolutions per minute for fifteen minutes. The contents of the tube should then appear as in the following description. The bottom of the tube contains a sediment. Above this sediment is the aqueous layer and above this is most often found a layer of nonfat material in the form of a button. In the event that there is an emulsion formed at the interface of the aqueous and ether layer, add a few more drops of alcohol, shake thoroughly, and recentrifuge. Above the button of nonfat material is found the layer of ether mixture. The formation of the button facilitates the removal of the ether layer.

The ether mixture layer is now aspirated off into a weighed beaker, care being taken to avoid contamination of the ether layer with the aqueous layer. Five milliliters of the ether mixture are again added to the tube. The tube is placed again in the shaking machine and centrifuged as before. The ether from the second extraction is added to that of the first and the mixture is evaporated to dryness on a steam bath. The beaker containing the residue from the drying of the ether is now brought to constant weight in a vacuum desiccator and weighed. A blank is run in similar manner without added stool. The blank should be negligible. If more than 0.2 mg of residue is obtained the solvents need to be redistilled.

If free fatty acid determinations are desired, 10 ml of ethyl alcohol are added to the beaker and it is heated to just below the boiling point of the alcohol. This dissolves the fats and the solution is titrated with 0.1N NaOH while still hot. A blank consisting of 10 ml of alcohol is titrated at the same time. The indicator used for both titrations is a 1 per cent solution of phenolphthalein in alcohol. If the equipment is available, electrometric titration may be substituted.

## CALCULATION

1 Weight of beaker and fat - weight of beaker = Weight of fat

2  $\frac{\text{Weight of fat}}{\text{Dry weight of stool sample}} \times 100 = \text{Per cent fat in stool}$

(Titration of fat - titration of blank)

3  $\frac{\times \text{normality} \times 268 \times 100}{\text{Weight of fat in milligrams}} = \text{Per cent fatty acids in fat}$

In the third equation the number 268 is derived from the average molecular weight of fatty acids assumed by Tidwell and Holt<sup>4</sup>

## DISCUSSION

The method described requires no special equipment other than a means of shaking large numbers of test tubes simultaneously. In this manner determination of stool fat can be used with greater frequency as a diagnostic aid even in laboratories possessing limited equipment. Further, large numbers of determinations may be done simultaneously without the necessity of handling cumbersome equipment. No separator funnels or Soxhlet extractors need be used.

From Table I it can be seen that the results as obtained on recoveries indicate an accuracy in the order of the more tedious methods.

Table II lists results on normal adults and children. These results are comparable to those previously reported on normal individuals.<sup>3</sup>

The method describes the determination of total fatty acids and total fat. No attempt to fractionate neutral soaps was made for it has been shown that the amount of free fatty acid is compared with neutral soaps varies with the method of drying the stool.<sup>3</sup> Kaye by a mild method of drying was able to get a higher percentage of free fatty acid for less was converted to calcium soaps than by more severe heating. Furthermore the ratio of sodium salts to fatty acids in stool is a function of the pH as would be expected from the basic equation

$$\text{pH} = \text{pK} + \log \frac{\text{Sodium salt of fatty acid}}{\text{Fatty acid}}$$

Thus, all the information required can be obtained from determinations of total fat, fatty acids, and pH. In our procedure the fatty acids are freed from combination with the alkali metals by shaking with the acid during the extraction.

This method has been in use in our laboratories for more than a year. During that time it has shown itself to be practicable and easily learned by the average technician.

## SUMMARY

1 A convenient method is described for the determination of fatty acids and fats in stool.

2 This method is simple, requiring no special equipment other than a shaking machine

3 The extraction is carried out in test tubes

## SIMPLIFIED EQUIPMENT FOR DETERMINATION OF UROBILINOGEN IN URINE AND STOOL

LAWRENCE E. YOUNG, M.D., R. WENDELL DAVIS, M.D., AND JANE HOGESTYAN, B.A.  
ROCHESTER, N. Y.

NUMEROUS observers<sup>1,2</sup> have in recent years stressed the usefulness of measurements of urinary and fecal urobilinogen in differential diagnosis and in following the course of certain diseases. Watson and associates<sup>3</sup> have described a simplified method for determination of urobilinogen which is quantitated by using a comparator block with pontacyl dye standards. This method has found extensive use but verbal reports indicate that many laboratories have not employed the procedure because of difficulties in preparing comparator blocks with materials at hand. The purpose of this paper is to describe the use of (1) a commercially available comparator block and (2) accessory equipment employment of which further simplifies this procedure.

### CONSTRUCTION OF EQUIPMENT

A commercially available comparator block,\* shown in Fig. 1 was adapted for use in estimating the Ehrlich reaction by inserting sealed vials of pontacyl dye solution in the designated places and sealed vials of distilled water in the alternate positions. The pontacyl dye standards were prepared according to the directions of Watson and co-workers<sup>4</sup> in such a way that their color densities corresponded to those developed in the Ehrlich reaction by the designated concentrations of urobilinogen.<sup>5</sup> Flat bottomed tubes in the comparator block have the same diameter as the vials containing water and pontacyl dye. Their capacity is 7 ml. and they have a single mark at 5 milliliters. Tubes and vials of larger diameter would provide greater accuracy in the lower range of density but those here employed have the advantages of compactness and current availability.

Several types of simplified pipetting equipment were subjected to intensive use by medical students in the hospital laboratory and as a result of such trials the pipettes with attached rubber bulbs shown in Fig. 1 were deemed best suited for this purpose. The pipette used for measuring urine or fecal filtrate and that used for transferring Ehrlich's reagent from bottle to tubes have single marks at 1.25 milliliters. The pipette used in measuring and transferring the solution of sodium acetate has a single mark at 2.5 milliliters.

From the Departments of Medicine and Pediatrics of the University of Rochester School of Medicine and Dentistry.

The observations described in this paper were made in part in connection with a contract between the University of Rochester and the Office of Naval Research.

Received for publication Oct. 2, 1948.

\*The comparator block was obtained from the W. A. Taylor Company, Baltimore Md. through the Will Corporation, Rochester, N. Y. As a result of the observations described in this report, the Will Corporation is now in a position to supply comparator blocks already filled with vials of dye standards and water. The accessory pipettes, rubber bulbs, cork stoppers, and widemouthed bottles are also procurable from the Will Corporation. (The catalogue number for the entire unit is 17185.) The solutions of dye are stable and if contamination and unnecessary exposure to light are avoided the color densities should remain unchanged indefinitely.

## METHODS

The equipment described is used as follows in determinations of urobilinogen by the methods of Watson and associates<sup>4, 5</sup>

*Two-Hour Specimens of Urine*—A two-hour urine specimen is collected in the middle of the afternoon when urinary urobilinogen excretion is usually maximal. The patient voids at 2 00 P M, discards the urine, drinks a glass of water, and voids at 4 00 P M. The volume of the latter specimen is recorded and the Ehrlich reaction is measured within one-half hour after voiding.

Fig 1—Comparator block and accessory equipment for measurement of urobilinogen

With the dropper pipette marked at 1.25 ml, this amount of urine is transferred to each of the two 5 ml tubes accompanying the comparator block. To one tube 1.25 ml of Ehrlich's reagent are added from the dropper bottle by use of the marked pipette. The contents are mixed by inversion and 2.5 ml of a saturated aqueous solution of sodium acetate are added without delay<sup>6</sup> and thoroughly mixed. To the other tube, which is to serve as the blank, the reagents are added to the urine in reverse order to prevent color development. First 2.5 ml of the solution of sodium acetate are added and the contents are mixed thoroughly, 1.25 ml of Ehrlich's reagent are then added slowly with constant shaking.

The blank and reaction tubes are placed in two adjacent openings in the comparator block and the sliding scale of dye standards is adjusted as necessary to bring the standard first selected for matching behind the blank and a vial of water behind the reaction tube as illustrated in Fig 2. If the match of colors obtained by holding up the set in front of a light is not satisfactory, a stronger or weaker color standard is moved into position behind the blank until the best match is found. Interpolation may be made if it is evident that the color intensity lies between two of the standards. If the blank develops a pink color or if the intensity of the unknown is higher than that of the color standard corresponding to a urobilinogen concentration of 0.6 mg per 100 ml further dilutions of the urine should be made, that is 1:2, 1:4, or 1:8, and so on, using the 1.25 ml drawn-out pipettes to measure urine and

distilled water into any ordinary test tube. The total amount of urobilinogen for the two hour period is calculated as follows:

Concentration of final solution in milligrams per 100 ml as determined from match with standards  $\times \frac{5}{1.25} \times \frac{\text{Milliliters urine excreted in 2 hours}}{100} \times \text{Any further dilution} = \text{Ehrlich units per 2 hours}$

Example  $0.20 \times 4 \times \frac{75}{100} = 0.60$  Ehrlich units per 2 hours

Fig 2—Cut away drawing of comparator block showing position of blank and unknown tubes in relation to tubes containing water and pontacyl dye standard

Normal adults usually excrete less than 10 Ehrlich unit during the two hour afternoon period. Results are expressed in Ehrlich units rather than in milligrams because nonurobilinogen chromogenic substances may contribute to the color measured by this simplified method.

If bilirubin is present in the urine it may interfere with the determination of urobilinogen, but in such cases the Ehrlich reaction can usually be carried out satisfactorily after merely diluting the urine with one or two parts of water. Porphobilinogen which is present in the urine of patients suffering from acute recurrent porphyria produces a pink aldehyde compound with Ehrlich's reagent, like that produced by urobilinogen. These two substances can be differentiated readily, however, by adding a few milliliters of chloroform to the reaction tube. The aldehyde compound of porphobilinogen remains in the aqueous fraction while that of urobilinogen is extracted by the chloroform, as shown by Watson and Schwartz.<sup>7</sup>

**Feces**—A 10 Gm aliquot of a single well mixed specimen is thoroughly ground with 90 ml of water. This is most easily accomplished by use of a Waring Blendor,<sup>8</sup> but an ordinary mortar and pestle will suffice. The fecal suspension is added to 100 ml of freshly prepared 20 per cent solution of ferrous sulfate (20 grams  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O} + 92 \text{ cc H}_2\text{O}$ ) in a 500 ml Erlenmeyer flask. Unless the specimen is acholic, 100 ml of water are added after first being used to rinse out the vessel such as the Waring Blendor used in pre-

paring the suspension One hundred milliliters of 10 per cent NaOH are then added slowly and with gentle shaking to the mixture in the Erlenmeyer flask The flask is stoppered and placed in the dark for one hour, or until the supernatant solution is nearly colorless, at the end of which time a small portion of the mixture is filtered The Ehrlich reaction is carried out on the filtrate in the same manner as with urine Dilution of the filtrate with water (most conveniently 1:10) is usually necessary unless the concentration of urobilinogen in the stool is low Calculation is carried out as follows

Concentration of final solution as determined from match with standards  $\times \frac{5}{1.25} \times \frac{400 \text{ (or 300)}}{10} \times \text{Further dilution} = \text{Ehrlich units per 100 Gm feces}$

Example  $45 \times 4 \times \frac{400}{10} \times 10 = 720$  Ehrlich units per 100 Gm feces

Normal adults excrete from 50 to 300 Ehrlich units per 100 Gm of feces For more accurate measurements of hemoglobin metabolism or of the degree of biliary obstruction, it is advisable to collect stools over periods of from two to four days and to determine fecal urobilinogen excretion per diem by use of the method of Schwartz, Sborov, and Watson<sup>9</sup> which includes extraction with petroleum ether The more elaborate method is also recommended for determinations of urobilinogen in twenty-four hour specimens of urine

Watson and co-workers<sup>4</sup> found that measurements of urobilinogen by use of the comparator block do not differ significantly from those made with a photoelectric colorimeter employing a 565 m $\mu$  filter Our experience with the commercially available equipment has been equally satisfactory Biologic variations, difficulties in collection of specimens, and the presence of chromogenic substances other than urobilinogen<sup>10</sup> undoubtedly affect the results of these determinations to a considerable extent Errors inherent in the use of the comparator block for routine clinical purposes are therefore considered inconsequential Since matching of densities of color is most difficult in the lower range (0.1 mg per 100 ml and below), it is advisable to use dilutions of filtrate if possible which will produce densities comparable to those found in the higher range on the block

In the Strong Memorial and Rochester Municipal Hospitals a comparator block and accessory equipment necessary for handling two hour urine specimens are placed in each divisional laboratory The more elaborate equipment, including corked tubes containing 20 Gm amounts of ferrous sulfate for preparing fecal filtrates, is located in a central laboratory This equipment, which is used by interns and medical students, is kept in sturdy boxes in order to minimize breakage and exposure to light and dust The boxes are inspected frequently, missing items replaced, and smeared comparator standards are cleaned with a damp cloth

<sup>10</sup>Nonurobilinogen chromogenic substances are eliminated by the more elaborate method of Schwartz, Sborov, and Watson<sup>9</sup> in which stercobilinogen and mesobilirubinogen are extracted by petroleum ether from filtrates of urine or feces In the present paper stercobilinogen and mesobilirubinogen are considered collectively as urobilinogen<sup>10</sup>

The equipment described has proved most useful in making serial measurements on two hour specimens of urine. Such determinations usually can be made in about two or three minutes, even by inexperienced personnel. Although the results are not strictly quantitative, they are much more easily interpreted than those obtained by the serial dilution method of Wallace and Diamond.<sup>11</sup>

## SUMMARY

A comparator block and accessory equipment for measurement of urobilinogen in urine and stool are described. This equipment has the advantages of commercial availability and simplicity.

# A SIMPLIFIED VACUUM DEHYDRATION TECHNIQUE FOR THE PREPARATION OF SECTIONS BY FREEZING-DRYING

K J WANG, M S , AND M I GROSSMAN, M D , PH D  
CHICAGO, ILL

THE technique of drying frozen tissue in vacuo at reduced temperature for the preparation of microscopic sections requires apparatus which is too elaborate and expensive to be employed in many laboratories (Geish<sup>1</sup>) The procedure described below for the preparation of the frozen-dried sections involves a simplified method for dehydration which can be applied at a considerable economy of time and materials

## I APPARATUS (FIG 1)

1 A Cenco-Supervac pump of the mercury vapor diffusion type (*A*) This pump operates by the application of heat from an electric heater (*B*) to the mercury in the boiler (Method of use is described in the directions in Catalogue No 93201 for the steel Supervac pump of the Central Scientific Company )

2 Forepump (*C*) The diffusion pump requires a forepump capable of keeping the pressure in the condensing chamber sufficiently low to insure vaporization of the mercury The Cenco Hvyvac Pump, Catalogue No 91105, is recommended for this purpose These pumps are kept continuously functioning during the period of dehydration

3 The Supervac pump and forepump are connected by a glass tube (*K*)

4 Heater (*B*) The boiler of the pump should rest evenly in the circular opening of the heater (*B*) The heater should be put into operation after the mercury pump has been evacuated by the forepump and after the cold water has been started circulating through the water jacket

5 The dehydration chamber (*D*) and the surrounding Dewar flask (*F*) A Pyrex test tube (*D*) (diameter,  $2\frac{1}{2}$  cm , length, 20 cm ) was used as the dehydrating chamber Drierite (8 mesh) ( $\text{CaSO}_4$ ) was placed in the bottom of the dehydrating tube to a height of about 2 cm as a drying agent to pick up the water as it comes off in the vapor state (*O*)

6 The connecting tube (*E*) A cylinder made of copper gauze containing a small amount of Drierite (*P*) was placed into the connecting tube (*E*) just before this tube was connected to the dehydrating tube *D*

7 The freezing trap (*G*) and the surrounding Dewar flask (*H*) In order to prevent mercury vapor from backing into the system being exhausted, a freezing trap (*G*) between the Supervac and the connecting tube (*E*) has been used This trap was surrounded by a mixture of solid carbon dioxide (dry ice) and acetone within a Pyrex silvered widemouthed Dewar flask (*H*), thus main

taining a temperature of about  $-80^{\circ}\text{C}$ . One end of the freezing trap was connected to the connecting tube (*E*), and the other end connected to the Supervac pump (*A*) by the connecting tube *I*.

8 All the connections should be made with the greatest care. After wrapping with para rubber tape (Cenco Catalogue No. 94220) the joint is covered with pure white shellac.

9 A high-frequency spark coil (Cenco Catalogue No. 80730) for testing vacuum assemblies for leakage was used after all the junctions were connected and the pumps had been started. Any leaks that were detected were repaired with additional rubber tape.

## II METHOD

1 Freezing. Tissue removed from the recently sacrificed animal was frozen in isopentane which was chilled in liquid air at  $-195^{\circ}\text{C}$  checked by a toluol thermometer. The isopentane should be stirred constantly to prevent it from becoming too viscous (Hoerr<sup>2</sup>). For most tissues dry ice and acetone ( $-80^{\circ}\text{C}$ ) can be substituted for the liquid air in cooling the isopentane.

2 Dehydrating. The frozen tissues were at once transferred to the drying tube (*D*), which had been cooled previously to  $-80^{\circ}\text{C}$  by solid carbon dioxide in the Dewar flask (*F*). During the transfer of the block to the cold dehydrating tube, the temperature of the block should not rise above  $-50^{\circ}\text{C}$ . After all the blocks are transferred to the dehydrating tube, it is then connected to the connecting tube (*E*) by para rubber tape, the forepump (*E*) is started and thirty minutes afterward the heater (*B*) of the mercury vapor pump (*A*) is turned on first starting cold water circulating through it at *J*.

3 To maintain the temperature of the vacuum dehydrating tube (*D*) at a temperature below  $-21^{\circ}\text{C}$ , we have used a very simple method. The method consists of surrounding the dehydrating tube with a Dewar flask (diameter,  $7\frac{1}{2}\text{ cm}$ , length, 26 cm) containing a large amount of solid carbon dioxide and a sufficient amount (near 2 lb) of dimethoxytetraglycol (Union Carbide and Carbon Corporation). Soon after mixing, this mixture will have a temperature of  $-80$  to  $-60^{\circ}\text{C}$ . The temperature of this mixture goes up gradually and becomes stabilized at  $-31^{\circ}\text{C}$  in from eight to twenty-four hours. Once the mixture reaches  $-31^{\circ}\text{C}$  it will maintain this temperature for a period of from two to three days. This property of dimethoxytetraglycol and dry ice mixtures was first pointed out by Wikoff<sup>3</sup>. The temperature should be checked with a toluol thermometer each day and a small amount of dry ice should be added when the temperature rises above  $-31^{\circ}\text{C}$ . An excess of dry ice should be avoided because it will bring the temperature below  $-31^{\circ}\text{C}$  and will prolong dehydration. Similarly a rise in temperature above  $-21^{\circ}\text{C}$  before dehydration is complete should be avoided, because collapse of the tissue and unsatisfactory fixation will result. In practice we have found that a single addition of a sufficient amount of dry ice to reduce the temperature to  $-31^{\circ}\text{C}$  on the third day of dehydration will result in good fixation for most specimens. The total length of the dehydration period is usually five days.

After the addition of dry ice on the third day, the temperature of the bath surrounding the dehydrating chamber is allowed to rise gradually toward room temperature usually reaching about  $-15^{\circ}\text{C}$  on the fifth day

4 Most of the water removed from the tissue during dehydration will be condensed in the freezing trap (*G*) and a part of the water in the dehydration tube is absorbed by the Drierite in the drying tube (*O*) Only a small portion of the water vapor is absorbed by the Drierite (*P*) in the connecting tube (*E*)

Fig 2—Low power photograph of the gastric mucosa of dog frozen in isopentane at  $-195^{\circ}\text{C}$  dried in our vacuum system at  $-31^{\circ}\text{C}$  Eight micron section stained by Hotchkiss method (polysaccharide staining with periodic acid) Shows uniformity of fixation and dehydration  $\times 170$

5 When the drying is completed the Dewar flask (*F*) surrounding the dehydration chamber is removed and the electric heater on the mercury pump is turned off The forepump is stopped about thirty minutes later The dehydrating tube (*D*) should be allowed to warm up to room temperature before the tissue is removed Usually half an hour will be sufficient, so the dehydration chamber can be opened at the time the forepump is turned off

6 Melted paraffin ( $58^{\circ}\text{C}$ ) is added to a warmed Erlenmeyer flask and the dehydrated tissues are placed in it to be infiltrated with paraffin by evacuation of the air in the flask by an ordinary oil pump, similar to the procedure of Gersh<sup>1</sup> Embedding and cutting are done in the usual way Fig 2 is a photomicrograph of a section of dog's stomach prepared by this method

## SUMMARY

A simplified method for the preparation of tissue sections by the method of freezing-drying is described. The method utilizes the constant temperature ( $-31^{\circ}\text{C}$ ) which a mixture of dry-ice and dimethoxytetraglycol will maintain over a long period of time as a means of holding the temperature of the tissue at a suitable level during dehydration.

## INTRODUCTION

FOR a number of investigations including fundamental studies of radiation effects on living tissues and therapeutic utilization of radioisotopes it is valuable to have methods for the selective localization of radioisotopes in certain tissues. Finely dispersed anhydrous chromic phosphate has been found useful by Jones, Wiobel and Lyons<sup>1</sup> in selectively irradiating the liver and spleen with  $P^{32}$  beta particles. The present studies, reported in this and the following communication,\* are concerned with methods for controlled selective localization of colloids (incorporating radioisotopes) in the liver, spleen, or bone marrow, and with an analysis of some of the factors involved in the phenomenon of localization.

*Choice of Elements for the Preparation of Colloids*—The elements zirconium, columbium, yttrium and lanthanum are particularly suitable for the present investigations. First it is possible to synthesize a variety of types of colloids incorporating radioisotopes of these elements. Second, there is available for these elements a large number of radioisotopes of differing nuclear properties. This group includes isotopes of short, intermediate, and long half-life, some of which emit only beta particles, some only gamma rays, and others both beta and gamma rays. Table I gives a description of the nuclear properties of the available radioisotopes.

*The Chemistry of the Preparation of Colloids of Zirconium, Yttrium, and Lanthanum*—Several types of colloids of the elements zirconium, yttrium, and lanthanum, varying in sign of charge, stability toward flocculation by added electrolytes, chemical structure, and particle size may be prepared. As is shown in the following communication, both the disappearance rate of such colloids from the blood stream of animals following intravenous injection and the site of uptake of the colloids can be made to vary through wide limits by

alterations in the nature of the colloidal aggregates. The chemical principles involved and the methods used in the preparation of several of the colloids used in this work are given below.

#### A. Preparation of Zirconium Colloids of "Relatively Large" Particle Size

1. *Zirconium oxide peptized in dilute nitric acid.* Owens<sup>2</sup> has shown that freshly precipitated hydrated zirconium oxide may be resuspended in dilute nitric acid (insufficient stoichiometrically to dissolve the hydrated oxide) to produce positively charged colloidal zirconium oxide. The effective peptizing agent is probably the zirconyl ion produced by the reaction of the zirconium oxide with hydrogen ions.

*Preparation.* 0.5 ml of 0.1M zirconium oxychloride solution (containing Zr<sup>95</sup> or Zr<sup>89</sup> tracer) is titrated to the phenol red end point with dilute sodium hydroxide, resulting in the quantitative precipitation of the zirconium. The hydrated oxide precipitate is centrifuged out, the supernate being discarded. The precipitate is suspended in 2.5 ml of 0.02M nitric acid and then shaken twelve hours in a mechanical shaker to peptize the zirconium oxide. Following this the mixture is centrifuged three minutes at ~500 G. The supernate from this centrifugation is the final colloidal solution. This sol is visibly cloudy, demonstrates a bright Tyndall effect, is polydisperse, and of such particle size that the majority of the suspended zirconium is sedimented in ordinary centrifuges at ~2,000 G in sixty minutes. Before use in biologic experiments this sol is mixed with an equal volume of 10 per cent dextrose solution to render it approximately isotonic.

## 2 Zirconium phosphate in dilute disodium acid phosphate

*Preparation* 0.1 ml of 0.1M zirconium oxychloride is mixed with 2.3 ml of 5 per cent dextrose solution and to this mixture is added 0.1 ml of 0.6M disodium acid phosphite. There results a turbid sol which demonstrates a marked Tyndall effect on illumination. No evident flocculation of the colloid occurs even after thirty minutes of heating at 100° C.

Glucose is present for the purpose of rendering the sol nearly isotonic, since 0.9 per cent saline solution produces immediate flocculation of the colloidal zirconium phosphate. Should foreign ions flocculate the colloid, repeated extraction of the precipitate with the original volume of 5 per cent glucose solution containing disodium acid phosphite (0.024M) results in colloidal resuspension of the zirconium phosphate.

*3 Zirconium oxide peptized in sodium lactate solution* 0.5 ml of zirconium oxychloride solution is titrated to the phenol red end point with dilute sodium hydroxide, the hydrated zirconium oxide centrifuged out, and the supernate discarded. The precipitate is suspended in 2.5 ml of 0.008M sodium lactate solution and shaken twelve hours to peptize the hydroxide. Centrifugation for three minutes at ~500 G removes the largest aggregates, leaving a supernatant sol that is visibly cloudy and shows a marked Tyndall effect. The mechanism probably operative in production of this type of colloid, namely zirconium lactate complex ion formation is fully discussed in the next section. This colloid is mixed with an equal volume of 10 per cent dextrose solution before being used in biologic experiments.

*B Anionic Colloids of Zirconium and Yttrium of Varying Particle Size* Zirconyl ions form complexes in aqueous solutions with triurate, lactate, and citrate ions of such stability thermodynamically as to prevent precipitation of the insoluble hydrated zirconium oxide even at relatively high hydroxide ion concentrations. Yttrium ions form complexes having similar properties with citrate ions.

It has been shown by Owens and Thomas<sup>3</sup> that the addition of such salts as sodium citrate, triurate or lactate to zirconium oxide hydrosols produces a marked rise in the pH of the hydrosol. This effect is attributed by them to the penetration of the micelles by the organic anions with replacement of hydroxide ions from the micelle, resulting in an increase in the free hydroxide ion concentration in the solution. Owens<sup>2</sup> has interpreted the conversion of positively charged hydrosols of zirconium oxide to negative sols in the presence of added citrate, tartrate, and lactate ions in the light of the above described complex ion formation and has shown further that by increasing the concentration of the complexing ion the colloidal aggregates may be broken down to particles diffusible through collodion membranes.

In our study of the zirconium hydroxide lactate (or triurate citrate) and of the yttrium hydroxide citrate systems it has been found that at a particular pH (e.g., 7.0), by controlled variations of the mole ratio of complexing ion to metal ion added to the solution, aggregates are obtained from the extreme of rapidly sedimenting macroparticles through smaller and smaller

\* Added as a solution of yttrium nitrate in water

† Added as sodium citrate solution

From the data in Table II it is seen that on reaching the ratio citrate/yttrium = 3 there is no hydroxide bound by yttrium. As would be expected from equilibrium considerations this continues to be the case at even higher citrate/yttrium ratios.

particles to aggregates whose sols (or solutions) no longer give a Tyndall effect. In any one of these preparations, the number of moles of hydroxide ion bound per mole of metal (zirconium or yttrium) varies with the number of moles of complexing ion present. Table II gives the titration values (moles hydroxide bound per mole yttrium) for yttrium in the presence of various total quantities of citrate ions (bound plus free) at  $\text{pH} 7$ . At the mole ratio yttrium/citrate = 2, and at  $\text{pH} 7$ , where 1.4 moles of hydroxide are bound per mole of yttrium one obtains rapidly sedimenting macroparticles. As the citrate/yttrium mole ratio is raised, the number of moles of hydroxide bound per mole of yttrium decreases sharply, and simultaneously the aggregate size drops from particles sedimenting rapidly, through those sedimenting more and more slowly then through those whose sols show an intense Tyndall effect without sedimentation at fields of  $\sim 2,000$  G down to those whose sols (or solutions) produce no Tyndall effect. Similar data for the yttrium-hydroxide citrate system at a final  $\text{pH}$  of  $\sim 8.3$  (phenolphthalein end point) are given in Table II.

TABLE III VARIATION IN CHEMICAL COMPOSITION AND PARTICLE SIZE IN THE YTTRIUM HYDROXIDE CITRATE SYSTEM WITH CHANGES IN THE MOLE RATIO OF YTTRIUM TO CITRATE AT pH = 8.3  
[Total Volume = 10 ml Final pH  $\approx$  8.3 (Phenolphthalein End Point)]

17	0.2	4.00	0.188	0.94	No precipitate no Tyndall effect in liquid

On comparing data in Table II with that in Table III it is seen that the hydroxide binding to yttrium is much more stable at pH 8.3 than at pH 7.0, so that at the higher pH even with citrate/yttrium ratios of 20:1, there is still approximately 1 millimole hydroxide bound per millimole of yttrium. Further, on comparing the products obtained at any particular citrate/yttrium ratio by using the pH from 7.0 to 8.3, it is noted that in addition to changing the extent of hydroxide/yttrium binding the particle sizes are smaller at pH 8.3 than at pH 7.0 (at least through the range of mole ratio of citrate/yttrium from 1:4 to 1:1). Qualitative experiments reveal that on still further increasing the pH (i.e. above 8.3) a region is reached where the aggregate size begins again to increase with pH increase.

It is evident from the above mentioned data that it is possible to prepare colloidal sols whose particle sizes may be made to vary through a wide range by altering the citrate/yttrium mole ratio at a particular pH. Or if a particular citrate/yttrium ratio is chosen one can vary particle sizes by altering the final solution pH. The aggregates obtained by the second of these procedures

are chemically different from those obtained by the first procedure, as is evident from the increased hydroxide binding at pH 8.3 compared with that at pH 7.0. Colloids prepared on the basis of these data may be used to investigate both the effect of particle size and of chemical structure upon such physiologic properties as blood stream clearance, rapidity of phagocytosis by elements of the reticulo-endothelial system, and site of uptake of the colloids *in vivo*.

In the case of zirconyl ions, in a system with hydroxide and citrate, tartrate, or lactate, a set of data similar to those for yttrium may be obtained by varying the ratio of complexing ions to zirconyl ion at any particular pH. One factor which differs is that the reaction between zirconyl ions and hydroxide ions at room temperature and above produces some bonds that, once formed, are very slowly broken by back titration. As a result, care must be exercised in preparing colloids of zirconium to add alkali slowly with adequate stirring, in the cold, to avoid such an occurrence during the process of titrating to the desired final pH value.

For several investigations described in the subsequent communication, colloidal preparations of zirconium and yttrium prepared according to the above-described principles have been used. In the case of both these elements, the colloidal particles thus prepared are much smaller than those in the preparations described in the section on "relatively large particle size" colloids. These latter sols, prepared according to the following directions, show only a faint Tyndall effect, and the particles are nonsedimentible using the centrifugal fields obtainable with ordinary centrifuges (2,000 G). Studies are now in progress to obtain a quantitative measure of particle sizes in such preparations as well as information as to particle symmetry and the extent of polydispersity of the sols. For the present the designation of "relatively large" particles and "intermediate" particles will be used without commitment as to actual particle diameters.

*C Preparation of Zirconium-Hydroxy-Lactate Colloid of "Intermediate" Particle Size* One milliliter of 0.4M zirconium oxychloride solution (containing the desired zirconium radioisotope) is mixed with 1.2 ml of 1.0M sodium lactate solution, 1 drop phenol red indicator solution is added, and the mixture diluted to 6.0 ml with water. This solution is then titrated carefully with 1M NaOH to the phenol red end point, always maintaining the temperature near 0° C. On heating this solution at 100° C the indicator color reverts to yellow. After ten minutes at 100° C, the solution is cooled to 0° C and again brought to the phenol red end point with NaOH. The alternate heating and cooling with repeated titration is continued until the end point (color) persists even after ten minutes of heating. This final solution is then diluted to 10 ml, heated at 100° C for ten minutes, and cooled. During the course of the titration to the phenol red end point it is imperative to avoid additions of alkali while the solution is warm for reasons previously mentioned in the general discussion. Colloids prepared according to these directions maintain their original properties at least over a period of two months when stored in ordinary rubber-capped Pyrex vessels.

*D Preparation of Yttrium Hydroxy Citrate Colloids* 0.5 ml of 0.2M  $Y(NO_3)_3$  solution (incorporating the desired yttrium radioisotope) is mixed with 0.16 ml of 0.5M sodium citrate solution, 1 drop phenol red indicator is added, and the mixture diluted to 2.0 ml with water. This solution is heated five minutes at  $100^\circ C$ . A precipitate will form at this step, or before heating, but the procedure is carried on without separating the precipitate, which later resuspends spontaneously. The solution is then titrated with 1.0M NaOH to the phenol red end point. On reaching the end point the solution is heated at  $100^\circ C$  for five minutes, cooled in ice water bath and if the end point has faded, is retitrated with sodium hydroxide. In contrast with the zirconium procedure, this retitration is necessary only once. The final solution is diluted to 4.0 ml and then heated one hour at  $100^\circ C$  in a rubber capped Pyrex serum bottle. Such colloidal preparations show no change in appearance or biologic properties over a period of four to six months. These colloids have been heated as long as eight hours at  $100^\circ C$  without demonstrating any change in properties.

*E Colloids of Lanthanum* Similar procedures have been utilized to prepare colloids in the lanthanum hydroxide citrate system, the qualitative details in this system being similar to those of the yttrium hydroxide citrate system, but with differences existing in the thermodynamic stability of the bonds involved. Since we have not yet studied the biologic properties of lanthanum colloids, the detailed chemical preparation is not given.

*F Colloids Containing Columbium* In using the radioisotope  $Zr^{93}$  (65 day half life), there is the problem of the 35 day  $Cb^{93}$  daughter isotope to consider. A chemical separation of the two isotopes can be made, but of course the  $Cb^{93}$  will soon regrow in the  $Zr^{93}$  preparation. We have investigated the zirconium colloids described in this communication using the  $Zr^{90}$  isotope (with a stable yttrium daughter), and using equilibrium mixtures of  $Zr^{90}$  and  $Cb^{90}$ . No quantitative differences in biologic behavior have been found, so that for these particular studies it appears that if the  $Cb^{93}$  isotope (without carrier) is incorporated into the zirconium colloid it shares the same metabolic fate as does the  $Zr^{93}$  isotope. For this reason no separation of these isotopes need be made for the particular purposes described in the following communications.

#### SUMMARY

1 For studies concerned with selective localization of radioisotopes in the bone marrow, liver, and spleen colloids incorporating such isotopes are useful.

2 Colloids of zirconium, columbium yttrium, and lanthanum have been chosen for study of selective localization of colloids because of the availability of radioisotopes of a wide range of nuclear properties and because of the comparative ease with which controlled variations in chemical structure and particle size of colloids containing these elements may be made.

3 The methods for preparing zirconium and yttrium colloids of various chemical types and ranges of particle size are described. A discussion of some of the chemical principles of these preparative methods is given.

### INTRODUCTION

SERIAL workers have shown that certain colloiddally dispersed materials are removed from the blood stream by the liver and spleen. Jones, Wiobel, and Lyons<sup>1</sup> have utilized suspensions of anhydrous chromic phosphate for the selective irradiation of the liver and spleen with  $P^3$  beta particles. Gersh<sup>2</sup> demonstrated that colloidal calcium phosphate is taken up by the liver and spleen. He stressed the failure of bone marrow phagocytes to take up this colloid in rats and dogs (though he referred to possible uptake in the marrow of rabbits under special conditions) and commented on the relative "refractoriness" in general of the bone marrow as compared with liver and spleen with respect to the uptake of colloidal dyes from the blood stream. Some histologic data<sup>3</sup> indicate that Thorotrast (a colloidal thorium dioxide preparation) is deposited in the bone marrow as well as in the liver and spleen, but no quantitative data as to the relative distribution are available.

In the preceding communication\* the methods for the preparation of colloids incorporating radioisotopes of yttrium, columbium, and zirconium were given. The present studies are concerned with the localization of such colloids primarily in the bone marrow or primarily in the spleen and liver, with an analysis of some of the factors which may be responsible for differences in localization.

1 *Selective Localization of Radioisotopes of Zirconium, Columbium, and Yttrium in the Liver and Spleen*—Several different colloids have been studied all of which show the common property of localizing in the liver and spleen of mice, rats, and rabbits. In every case the colloids having this distribution are those of "relatively large" particle size, sedimentable in large part in ordinary centrifuges. These sols are turbid and produce an intense Tyndall effect on illumination. Further, in general, for the colloids which localize in the liver and spleen, the disappearance rate of intravenously injected colloid from the blood stream is rapid, the blood colloid level decreasing approximately exponentially with time, the half time for blood clearance (and liver

Fig 1

and spleen uptake) being in the neighborhood of 30 seconds to 1 minute. Representative distribution data for the three colloids—(1) zirconium oxide peptized in nitric acid, (2) zirconium phosphate peptized in disodium acid phosphate and (3) zirconium oxide in dilute sodium lactate—in the mouse are given in Table I. The preparative procedure for these colloids is given in the preceding communication.

In the case of all of these colloids the blood disappearance curves show a small percentage (between 1 and 10 per cent) of more slowly clearing components in addition to that component having the  $T_1$  of 30 seconds to 1 minute. The methods of preparation for these sols are such that polydispersity of the sols is expected. Several types of experimental data lend support to the idea that the smaller particles in such polydisperse sols are responsible for the slowly clearing fraction. First, experiments have been performed, using the mouse, where a colloid having  $\sim 1$  per cent of the total activity in the slowly disappearing fraction has been centrifuged to remove the larger particles.

Fig 2

The supernatant colloid was then injected and was shown to have a slowly disappearing fraction of  $\sim 8$  per cent. These data appear to support the idea that the smaller particles constitute the slowly disappearing fraction. Further experiments with a colloid of zirconium oxide suspended in sodium lactate were done in the rabbit. Fig 1 gives the blood disappearance curve\*. This particular preparation has an appreciable percentage of slowly clearing components in addition to the major fraction of very rapid blood clearance rate.

\*The rapid disappearance rate cannot be interpreted as simply due to mixing phenomena, since much evidence accumulated shows that in the rabbit mixing phenomena are of negligible proportions after one minute. The data used in Fig 1 demonstrate rapid disappearance after this mixing period. Figs 2 and 3 demonstrate that mixing phenomena do not result in an apparently rapid disappearance curve at times after one minute following injection.

BLOOD STREAM DISAPPEARANCE FOR INTERMEDIATE PARTICLE SIZE COLLOID IN THE RABBIT

Fig 3

At two hours after injection (A, Fig 1), when all the rapidly disappearing fraction had been cleared, serum was collected and the rabbit sacrificed. The serum containing the slowly disappearing component was injected into a second rabbit. The second rabbit was sacrificed after its blood had been cleared, and the tissue distribution of the colloid was determined. The data are given in Table II.

TABLE II

ORGAN	DISTRIBUTION OF ZIRCONIUM COLLOID IN INITIAL RABBIT (INCLUDING RAPIDLY CLEARING FRACTION) (% INJECTED DOSE IN ENTIRE ORGAN)	DISTRIBUTION OF ZIRCONIUM ACTIVITY IN ANIMAL INJECTED WITH SERUM FROM INITIAL ANIMAL (% INJECTED DOSE IN ENTIRE ORGAN)
Bone plus marrow	9.3	43.0
Liver	85.0	23.0
Spleen	3.2	3.0
Muscle	1.3	17.0
Lungs	1.0	---
Kidney	0.3	14.4

It is seen that the liver received the major fraction of the rapidly clearing colloid, whereas the bone plus bone marrow received the major fraction of the slowly clearing colloid component. Thus in all the experiments tabulated (and in several others for similar colloids) where the colloidal particles are relatively large in size sedimentable in large part even with ordinary centrifuges producing sols that are turbid and demonstrate an intense Tyndall effect we have found the blood clearance rate to be very rapid ( $T_1 = 30$  seconds to 1 minute) and the site of uptake of the colloid to be the liver and spleen primarily. From the magnitude of the blood clearance rate it is certain that much of the colloid is cleared in a single passage through the liver so that for these colloids the rate of blood flow through the liver relative to that through the bone marrow probably plays a major role in securing localization of the colloid in the liver plus spleen rather than in the bone marrow. For chromic phosphate suspensions also it is now known that there is association of relatively large particle size rapid blood clearance and liver and spleen localization just as with the above described zirconium colloids. The mechanism responsible for the rapid uptake by the liver and spleen of relatively large particles is not yet clear nor has the significance of factors other than particle size alone been evaluated in determining blood clearance rate and site of uptake of the colloids.

*B Selective Localization of Radioisotopes of Zirconium, Columbium and Yttrium Primarily in the Bone Marrow, and Secondarily in the Spleen and Liver*—As described in the preceding communication zirconium colloids of zirconium and yttrium may be prepared of much smaller particle size than those just shown to deposit primarily in the liver plus spleen. These colloids are of the zirconium hydroxy lactate and the yttrium hydroxy citrate type. In contrast to the rapid blood clearance of the "relatively large size" aggregates these latter colloids of intermediate particle size are cleared much more slowly in the rabbit, rat, cat and mouse showing exponential decay from the blood stream with half times from 30 to 80 minutes (see Figs. 2 and 3) the colloid remaining quantitatively in the plasma until cleared. In the rabbit, rat, and cat the slowly disappearing colloids localize primarily in the bone marrow, with spleen and liver receiving the next highest quantity (all expressed on specific activity basis)\*. The distribution data in the rabbit for the zirconium hydroxy lactate colloid are given in Table IV and for yttrium hydroxy citrate colloid in Table III. In the case of zirconium and yttrium colloids which localize primarily in the bone marrow we find associated these features: (1) particle size much smaller than in those colloids localizing primarily in the spleen and liver (less pronounced Tyndall effect noncentrifugability with ordinary centrifuges) (2) slow disappearance from the blood stream ( $T_1 = 30$  to 80 minutes contrasted with 30 seconds to 1 minute for "liver and spleen" colloids).

\* In the mouse the liver and spleen take up the major fraction of the slowly disappearing colloids although the bone marrow uptake is greater than for the large particle colloids.

TABLE III DISTRIBUTION OF INTRAVENOUSLY INJECTED YTTRIUM HYDROXY CITRATE COLLOID IN THE TISSUES OF THE RABBIT ("INTERMEDIATE" PARTICLE SIZE)  
(Half Time for Blood Stream Clearance = 70 min )  
(Animal Sacrificed 18 hr After Injection)  
(Y<sup>91</sup> Tracer — 10 cc Injection)

\*A mixture of Zr<sup>90</sup> and Cb<sup>94</sup> radioisotopes was used in preparation of this colloid. The distribution data differed in no significant details from that for Zr<sup>90</sup>, a positron emitter, the yttrium daughter of which is stable, indicating that the Cb<sup>94</sup> radioisotope shares the metabolic fate of the zirconium colloid.

particle sizes of these types, it is planned to try to gain some insight into the possible effect of variations in chemical composition (at the same particle size) on blood stream disappearance rate and site of uptake of colloids, and thus perhaps obtain a clearer idea of the mechanism operative in selective localization in one element or another of the reticulo-endothelial system. From the present data it is not possible to determine whether or not polymerization of the slowly disappearing colloids is a necessary preliminary to reticulo-endothelial deposition or whether the particles remain in the serum at the original size and are slowly removed at this size.

*C Retention of Yttrium and Zirconium Colloids in Tissue Following Initial Uptake*—For several applications of such colloids in selective irradiation it is necessary to know to what extent the colloids remain fixed in tissues once deposited.

TABLE V PATENT OF RETENTION OF YTTRIUM HYDROXY CITRATE AND ZIRCONIUM HYDROXY LACTATE COLLOIDS IN TISSUES OF DEPOSITION IN THE RABBIT

ORGAN	INJECTED DOSE STILL PRESENT IN ENTIRE ORGAN					
	YTTRIUM HYDROXY CITRATE COLLOID		ZIRCONIUM HYDROXY LACTATE COLLOID			
	DAYS AFTER INJECTION					
	2/3	11	1/6	1	10	22
Bone and marrow	3.0	3.0	44.0	46.0	35.0	34.0
Spleen	1.0	0.4	1.3	2.9	1.8	1.1
Liver	45.0	29.0	37.0	21.0	24.0	22.0
Kidneys	1.0	0.7	2.7	2.0	3.1	2.3
Lungs	0.5	0.3	0.4	0.9	0.6	0.3

\*Data in this table were obtained by injecting separate rabbits with the colloids and sacrificing the animals at the stated time intervals after injection.

For the zirconium phosphate colloids (large particle type) in the mouse, analysis shows that there is at ten days after injection 96.5 per cent of injected zirconium in liver plus spleen, 0.3 per cent in the lungs, and 3.3 per cent in the entire remainder of the carcass. Comparison of these data with those for the same colloid in Table I shows that no significant loss of activity or change in distribution occurs for this colloid over this time interval.

Similar data for the yttrium hydroxy citrate and zirconium hydroxy lactate "intermediate particle size" colloids are given in Table V.

Excretion data in the rabbit show negligible losses of yttrium colloid via the urine after the first day while  $\frac{1}{2}$  to 1 per cent of the injected dose is lost daily via the feces.

Except for a possible trend toward slow loss of activity from the liver, it is seen that the bulk of the yttrium and zirconium colloids tend to remain localized at the site of deposition, at least for the periods of time given in Table V.

*D Experimental and Therapeutic Applications*—For experimental work requiring specific irradiation of the liver, spleen, or bone marrow or combinations of these organs the colloids described are useful. With the range of short and long lived radioisotopes of yttrium, zirconium, and columbium

available and with the evidence presented that colloids incorporating such isotopes may be retained in tissues of deposition for at least several weeks, it is possible to achieve continuous specific irradiation of tissue at any desired intensity level either for short or long periods of time

In certain neoplastic diseases of the hematopoietic system, as the leucemias, myelomas, or other neoplasms involving the liver or bone marrow, and in polycythemia, the therapeutic use of yttrium or zirconium colloids seems feasible. With these colloids irradiation is localized in these tissues while minimizing the irradiation of other tissues. With a range of half lives of beta-emitting isotopes from 17.0 hours to 65 days, one may have a great latitude in choosing duration and intensity of therapeutic irradiation. A clinical evaluation of these colloids, with incorporated radioisotopes, is now being made both with respect to tissue distribution in human beings and with respect to therapeutic efficacy in polycythemia, the leucemias, and certain other selected diseases. While no great differences from other forms of radiation therapy are anticipated, it is possible that some improvement in the management of these diseases may result.

#### SUMMARY

1 Colloids of zirconium of relatively large particle size show rapid disappearance from the blood stream ( $T_{1/2} = \sim 30$  seconds to 1 minute) and are deposited mainly in the liver and spleen.

2 Colloids of smaller particle size, both of zirconium and yttrium, disappear much more slowly from the blood stream ( $T_{1/2} = 30$  to 80 minutes) and are deposited primarily in the bone marrow and spleen, secondarily in the liver—the liver specific activity being approximately one-third that of marrow.

3 Both types of colloids, once deposited in these organs, show no significant change in distribution pattern, at least over a period of two to four weeks, and only slow excretion from the body.

4 The distribution of the colloids and the availability of the isotopes of a wide range of nuclear properties render them suitable for experimental studies requiring specific irradiation and for therapeutic utilization in certain diseases.

# AN EXPERIMENTAL STUDY OF THE EFFECT OF ZIRCONIUM AND SODIUM CITRATE TREATMENT ON THE METABOLISM OF PLUTONIUM AND RADIOTRITIUM

JACK SCHUBERT, PH D  
CHICAGO, ILL

## INTRODUCTION

THE routine processing and handling of large and ever increasing quantities of radioelements are now in actuality. When these radioelements find their way into the body they may cause radiation injury in a manner similar to radium poisoning. Internally fixed radioelements are of special concern since the amounts needed to produce injury are trifling compared with the quantities necessary to cause equivalent damage from external sources of radiation. Most of these potentially dangerous radioelements are metals. The purpose of this and subsequent studies is the development of rapid, safe, and effective procedures for increasing the elimination of potentially harmful radioelements which have gained entry into the body. The magnitude and nature of the problems involved have been described ably by Hamilton and associates.<sup>1, 2</sup>

It has been postulated and shown that the excretion of certain metallic elements fixed in the body should be increased following the administration of relatively large amounts of the soluble salts of certain other metals. The citrate salt of zirconium when given to rats was found to cause a considerable increase in the urinary excretion of plutonium and a large decrease in the amount of plutonium deposited in the skeleton. An investigation of the effects of zirconium citrate and salts of other metals on the excretion and distribution of a large variety of radioelements is now being conducted in this laboratory. The present study provides a direct comparison of the very marked displacing action of zirconium citrate on plutonium ( $\text{Pu}^{239}$ ) and tritium ( $\text{T}^{91}$ ). Since  $\text{T}^{91}$  is a beta emitter and  $\text{Pu}^{239}$  an alpha emitter, it was advantageous to administer these elements simultaneously and to analyze for each element directly in the presence of the other without the necessity of carrying out any chemical separations.

## EXPERIMENTAL

*General Procedures*—The experiments described in this paper utilized 200 gram Sprague Dawley female rats and a growing mongrel dog. Experimental details which relate to the dog will be described later. The rats were kept individually in metabolism cages which were especially constructed to facilitate the daily collection of urine and feces separately. All injections

From the Medical and Biology Divisions of the Argonne National Laboratory.  
This paper is based on work performed under Contract No. W-31-109 eng 38.  
Received for publication Nov. 17, 1948.

were made by the intraperitoneal route. Eight rats were given a single injection of 20 ml of the  $\text{Pu}^{239}$  plus  $\text{Y}^{91}$  solution. Thirty minutes later three of the animals were administered 40 ml of the zirconium citrate solution (a total of 51.4 mg as  $\text{Zr}$ ) and two others were given 40 ml of a 5 per cent sodium citrate solution (early treatment). Of the remaining three control rats, one was given 40 ml of the zirconium citrate solution seventy-two hours after the administration of the radioelements (late treatment).

The rats were sacrificed six days after receiving the radioelements. The liver, spleen, kidneys, femurs, and carcass were analyzed separately.

**Radioelement Solution**—The radioelement solution was at a pH of 5.6 and had the following composition per milliliter: 40  $\mu\text{g}$  of  $^{239}\text{Pu}$  ( $2.7 \times 10^6$  counts per minute under the counting conditions), 2.3  $\mu\text{c}$  of  $\text{Y}^{91}$  ( $1.3 \times 10^6$  counts per minute under the counting conditions), 2 per cent citric acid, 0.15M in  $\text{Na}^+$  and 0.05M in  $\text{Cl}^-$ .

**Preparation of the Zirconium Citrate Solution**—The zirconium was converted to a soluble citrate complex form. The solution of this complex salt is stable toward wide changes in temperature, pH, dilution, and to phosphate ion. A 100 ml batch is prepared as follows: To 18 ml of a filtered solution of zirconyl chloride ( $\text{ZrOCl}_2$ ) containing 130 to 140 mg as  $\text{Zr}$  per milliliter add, while stirring, 80 ml of a 12.5 per cent solution by weight of sodium citrate,  $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7 \cdot 2\text{H}_2\text{O}$ . A precipitate which first forms, presumably zirconium hydroxide, subsequently dissolves. Two milliliters of a 20 per cent solution of  $\text{NaOH}$  are added and the zirconium citrate solution is filtered through quantitative filter paper. The final solution is clear and colorless. It has a pH of  $\sim 6.3$  and contains about 25 mg as  $\text{Zr}$  per milliliter and the equivalent sodium and citric acid concentration of a 10 per cent sodium citrate solution. Because of its hypertonicity ( $\sim 1\text{M}$  in  $\text{Na}^+$ ) it is advisable to dilute the solution at least 1:1 with distilled water, as was done in the present experiment. For intravenous injection a fourfold dilution yielding a near isotonic solution and 6 mg as  $\text{Zr}$  per milliliter is preferable.

TABLE I EXCRETION OF ZIRCONIUM IN RATS FOLLOWING INTRAPERITONEAL ADMINISTRATION OF ZIRCONIUM CITRATE

DAYS ELAPSED AFTER FIRST ZP INJECTION	TOTAL MG AND PER CENT OF TOTAL INJECTED DOSE OF ZR							
	RATS INJECTED WITH 100 MG ZR ON 0 AND 3RD DAY				RATS INJECTED WITH 50 MG ZP ON 0 AND 1ST DAY			
	URINE		FECES		URINE		FECES	
	MG	%	MG	%	MG	%	MG	%
0 1	78	78	0.05	0.05	43.5	87	<0.05	<0.1

2 3	0.3	0.3	---	---	0.5	0.5	---	---
3 4	90	45	0.4	0.2	0.7	0.7	---	---
4 5	1.6	0.8	0.4	0.2	0.5	0.5	0.2	0.2
5 6	1.4	0.7	2.0	1.0	0.8	0.8	2.0	2.0
7 8	0.2	0.1	0.6	0.3	0.05	0.05	<0.05	<0.05
9 10	0.06	0.03	---	---	0.4	0.4	---	---
11-12	0.2	0.1	0.1	0.05	0.3	0.3	<0.05	<0.05
13 14	0.2	0.1	0.06	0.03	0.3	0.3	---	---
	173	87	$\sim 4.4$	$\sim 2.2$	91	91	$\sim 2.9$	$\sim 2.9$

The zirconium in this solution is part of an anion complex and the approximate formula of the chelated compound<sup>6</sup> formed is  $\text{Na} [\text{ZrO}(\text{C}_6\text{H}_5\text{O}_7)]$

*Excretion of Zirconium*—In a separate experiment the excretion rate of the zirconium citrate was studied (Table I). Within the first twenty-four hours following the administration of zirconium citrate, the bulk of the dose is excreted in the urine. The analyses for zirconium were made by gravimetric method in which the phosphate of zirconium is precipitated from 10 per cent sulfuric acid.<sup>3</sup>

*Toxicity of Zirconium and Other Metals*—In rats the zirconium citrate salt appears to be innocuous and does not seem to result in chronic intoxication.<sup>4</sup> Large frequent doses as high as 1.5 Gm per kilogram as  $\text{Zr}$  did not cause any deaths. Investigations with a similar citrate salt of zirconium showed that the LD<sub>50</sub> for acute toxic levels is 1.7 Gm as  $\text{Zr}$ .<sup>4</sup> As much as 3.6 Gm per kilogram of  $\text{Zr}$  is tolerated by rats when administered once daily in doses of 0.45 Gm per kilogram.

The possibility of using La, Ce and Cb for metal displacement studies was tested. However, it was found that as little as 12 mg per kilogram of the chlorides of La and Ce proved fatal to rats within three days when given intravenously. Fifty milligrams of Cb per kilogram in the form of sodium columbate gave rise to symptoms of severe intoxication of a chronic nature.

*Methods of Analysis*—The excreted and weighed tissues were prepared for analysis by repeated ashing with concentrated  $\text{HNO}_3$  and 30 per cent  $\text{H}_2\text{O}$  until a white ash remained. The ash was dissolved in 3M  $\text{HNO}_3$  and the solution transferred to a volumetric flask and made up to volume. The urine samples obtained on the day following zirconium administration contained a considerable amount of insoluble oxides of zirconium. In such cases the solutions were well shaken before an aliquot for counting was taken so as to include a proportional amount of the suspended material.

The samples were assayed for  $\text{Y}^{91}$  activity by directly counting a dried aliquot through a thin mica end window Geiger tube. The samples for  $\text{Pu}^{239}$  activity were mounted on a  $1\frac{1}{2}$  inch platinum disc and the alpha activity was determined in a proportional  $\alpha$  counter. The dried sample weights were kept to a minimum in order to prevent significant losses through self absorption. Adjustments were made to insure that no  $\text{Y}^{91}$  beta activity was being recorded in the alpha counting circuit. The alpha or beta activity in a sample was periodically referred to a sample from the original injection solutions which were mounted and counted in an identical manner. Aliquots of the samples from the original injection solutions were obtained after making several dummy injections into a volumetric flask.

#### RESULTS OBTAINED WITH RATS

*Comparison of Normal Pu and Y Metabolism*—The fact that the Pu and Y were administered simultaneously affords a unique opportunity for directly comparing the metabolism and distribution of these elements under identical circumstances.

<sup>6</sup> The chelate nature of the compound and its probable formula is based on information communicated by Dr. Loren C. Hurd of the Rohm and Haas Company, Philadelphia, Pa.

Actually the salt is sodium zirconyl citrate but for our purposes it is convenient to refer to it as zirconium citrate.

\*Values equated to 100 per cent (actual recoveries averaged 89 plus-minus 5 per cent)

†Each value is an average of results obtained from two rats for the untreated controls, two rats for the sodium citrate treated three rats for the early zirconium citrate treated, and one rat for the late zirconium citrate treated.

The sodium citrate treated rats received 1 ml of a 5 per cent solution one half hour after receiving a 2 per cent sodium citrate solution of  $Y^{90}$  plus  $Pu^{239}$  while the early zirconium treated rats received 51 mg  $as\ Zn$  one-half hour after the  $Y$  plus  $Pu$  solution. The late zirconium treated rat received 51 mg  $as\ Zn$  three days after the  $Y$  plus  $Pu$  solution. All injections were made by the intraperitoneal route.

Considerable differences in their behavior were shown especially in the urinary excretion and retention by the liver (Table II)

During the six day period the rats excreted in the urine nearly twenty times as much Y as Pu (27 per cent and 1.4 per cent respectively). On the other hand, the fecal output of Pu was about twofold greater than the fecal

### DISTRIBUTION AND EXCRETION OF PLUTONIUM ( $\text{Pu}^{239}$ ) IN UNTREATED AND TREATED RATS

Fig 1—Effect of zirconium and sodium citrate treatment on the distribution and excretion of Pu ( $\text{Pu}^{239}$ ) in rats six days after the intraperitoneal administration of the radioelement.

excretion of Y. The ratio of urinary to fecal excretion one day after injection was about 20 for Y and about 0.5 for Pu. At the sixth day after injection the ratio was approximately 1 for Y and 0.04 for Pu. These ratios emphasize the differences in the nature of the excretion between these two elements.

The kidney retained more than twice as much Y as Pu while the liver retained about eight times more Pu (11.9 per cent and 1.5 per cent respectively). The deposition of Pu in the skeleton was 1.7 times as great as that of Y as

# DISTRIBUTION AND EXCRETION OF YTTRIUM ( $Y^{91}$ ) IN UNTREATED AND TREATED RATS

Fig 2—Effect of zirconium and sodium citrate treatment on the distribution and excretion of  $Y^{91}$  in rats six days after the intraperitoneal administration of the radioelement.

indicated by the femur content. No significant differences in the amounts deposited in the spleen were found. The carcass, which included the pelt, muscle, blood, skeleton, and gastrointestinal tract retained 72 per cent of Pu and 62 per cent of the Y. With respect to Pu the results obtained are in good quantitative agreement with those reported by Cairnt and co-workers.<sup>6</sup>

The differences in excretion and distribution between Pu and Y are probably indicative of the greater tendency of Pu to become colloidal in the physiologic pH region. This point is discussed later in the paper.

*Effect of Treatment on the Urinary and Fecal Excretion of Pu and Y*—The over-all distribution and excretion of plutonium and yttrium in treated and untreated rats at the end of the six-day period are summarized in Table II and presented graphically in Figs 1 and 2. The daily excretion levels are shown in Figs 3, 4, and 5. During the six-day period the rats lost about 5 per cent of their body weight.

EFFECT OF ZIRCONIUM AND SODIUM CITRATE TREATMENT ON THE DAILY URINARY EXCRETION OF  $\text{Pu}^{239}$ 

Fig 3—See text for information regarding the injections

Following a single injection of 51.4 mg of Zr the urinary excretion of Pu in the early treated rats was increased from about 1 per cent of the total injected dose to about 50 per cent, a factor of 50. At the same time the urinary excretion of Y was increased from about 25 per cent to 60 per cent, or nearly two and one half fold. Of interest is the fact that the urinary excretion of Pu (and to a lesser extent of Y) continued to be appreciably greater than that of the control animals for the succeeding five days (Figs 3 and 4). The sustained nature of the heightened urinary excretion of Pu confirms earlier findings.<sup>2</sup> When a single injection of 51.4 mg of Zr was administered three days after the Pu and Y, the urinary excretion of Pu was still increased to a remarkable extent, namely from 0.08 per cent to more than 5 per cent, a factor of more than 60. Similarly, the excretion of

# EFFECT OF ZIRCONIUM AND SODIUM CITRATE TREATMENT ON THE DAILY URINARY EXCRETION OF $Y^{91}$

Fig 4—See text for information regarding the injections

$Y$  was increased about tenfold, viz 0.3 per cent to  $2\frac{1}{2}$  per cent. Sodium citrate did not appear to significantly change the urinary excretion of Pu or  $Y$ .

The fecal excretion of Pu or  $Y$  was little affected by zirconium or sodium citrate administration. In the case of  $Y$  early treatment increased fecal excretion by a factor of 2 over the six-day period while that of Pu was not significantly changed (Fig 5).

*Effect of Treatment on the Body Distribution of Pu and  $Y$* —The amount of Pu and  $Y$  deposited in the skeleton was remarkably reduced following the early administration of a single injection of zirconium citrate. The Pu content in the femurs decreased from 7.3 per cent to 1.2 per cent, a reduction of

EFFECT OF ZIRCONIUM AND SODIUM CITRATE TREATMENT ON THE DAILY FECAL EXCRETION OF  $\text{Pu}^{239}$  AND  $\text{Y}^{91}$ 

Fig 5—See text for information regarding the injections

sixfold, while that of Y was decreased from 42 per cent to 16 per cent a factor of 2.6. In the rats treated with Zr three days after exposure, a small decrease in skeletal Pu but not of skeletal Y was observed. The amounts of Pu and Y retained by the carcass in the early treated rats were reduced by a factor of about 2.3.

No significant changes in the amounts of Pu and Y deposited in the spleen, liver, or kidneys were found following administration of zirconium citrate. In a previous experiment it was found that the amount of Pu deposited in the liver was reduced by a factor of 2 to 3 following Zr administration. However, the fact that the animals in the previous experiment were sacrificed eighteen days after the administration of Pu and Zr may be responsible for the difference. It is of interest to add that in the previously reported experiments no change in the amount of Pu deposited in the lungs was noted following administration of zirconium citrate.

Hamilton and co workers<sup>5</sup> have carried out experiments on the effect of zirconium citrate on the distribution and excretion of rats injected intramuscularly or intravenously with plutonium or yttrium. The results of these experiments are in good agreement with those reported here.

Fig 6—Effect of zirconium citrate on the rate of excretion of Pu by a growing dog following intravenous administration of 0.423 mg of Pu (IV). The zirconium citrate was given intravenously. The dog weighed 7.3 kg when injected, 11.5 kg 150 days after the Pu injection and 12 kg after 890 days.

#### RESULTS OBTAINED WITH A GROWING DOG

A growing mongrel dog weighing 7.27 kilograms was injected intravenously on Oct 25, 1945, with 0.423 mg of Pu (0.058 mg per kilogram) in the form of  $\text{Pu}(\text{IV})$  nitrate. The rate of urinary and fecal excretion of Pu was quite rapid during the subsequent two weeks and then reached a nearly constant level about thirty days after the administration of Pu (Fig 6). During the two weeks immediately following the injection of Pu the dog excreted 1.1 per cent of the injected dose in the urine and 2.7 per cent in the feces, or a total of 3.8 per cent. On the thirtieth day after the injection the average urinary excretion of Pu was 0.007 per cent of the injected dose. The average daily fecal excretion of Pu was about 0.0085 per cent and the ratio of average urinary to fecal excretion was 0.8. This ratio is in substantial agreement with data obtained with human subjects at thirty days.<sup>6</sup> Four months after injection the urinary and fecal excretion of Pu was essentially unchanged from the thirty-day value. It is of interest to note that at this time the concentration of Pu per milliliter of circulating blood was  $0.025 \mu\text{c}$  or  $10^{-4}$  per cent of the injected dose.

Five months after the dog received Pu, intravenous administration of small amounts of zirconium citrate was begun. At this time the dog's weight was 11.5 kilograms. An injection of only 4.15 mg per kilogram of Zr was followed by a definite increase in the urinary excretion of Pu (Fig. 6). Subsequent larger doses of zirconium citrate indicated that the extent of the increase in the excretion level of Pu was proportional to the amount of Zr injected. The increase in the excretion level was greatest during the few days immediately following the administration of zirconium citrate. However, the increased rate of excretion was continued for at least two to three weeks after cessation of Zr treatment. Following injections of 4.15, 7.85, and 15.8 mg per kilogram of Zr the average per cent increase in Pu excretion on the tenth day after each Zr injection was 35, 75, and 165 per cent respectively. Inasmuch as the dosage levels of Zr were considerably less than the maximal dose, probably by a factor of at least 10 to 100, it appears that the biologic half-life of Pu in the body can be reduced to a significant extent even in cases of chronic poisoning. The fact that the treated dog had undergone a 60 per cent increase in body weight by the time the zirconium citrate was administered speaks well for the effectiveness of the treatment because the burying or overlying of the deposited Pu by newly laid tissue would probably tend to decrease the displacing action of Zr.

Nearly two and one half years after the injection of Pu the urinary excretion level had dropped to 0.002 per cent of the injected dose. This is probably lower than would be the case if the dog had reached its full growth before receiving plutonium for the above mentioned reason. It is of interest to note that injection of 17 mg per kilogram of Zr at this late date was followed by a twofold increase in the urinary excretion of Pu.

The fecal excretion of Pu was scarcely affected by the administration of zirconium citrate.

#### DISCUSSION AND GENERAL THEORETICAL CONSIDERATIONS

The distribution and excretion of metals are, in many instances, greatly dependent upon the route of administration, the chemical state of the metal, and the solvent. With metals possessing colloidal tendencies these factors are even more critical. The effectiveness of zirconium citrate treatment for any one metallic radioelement may vary considerably, particularly with those having colloidal tendencies. In interpreting the behavior of cationic elements in the body it is necessary to consider their chemical properties very closely, especially those relating to the formation of hydroxides, soluble complex ions, and insoluble compounds.

A radioelement is bound to various tissues by chemical or physical forces or a combination of the two depending on the environment. The displacement process is essentially an exchange reaction. When the exchange reaction is ionic in nature then the displacing property of a cation is dependent upon its concentration, valence and hydrated radius, and bodily distribution. The higher the valence and concentration and the smaller the hydrated radius

the greater is the displacing ability. The ideal cation should combine maximum displacing properties with a minimum toxicity. Furthermore, its displacing action should be sustained for long periods. Thus a metallic cation which is not destroyed by metabolic processes would be preferable to metabolizable substances such as citrates and acetates.

Some cationic radioelements are bound to surfaces by insoluble compound formation, as, for example, with bone phosphate. In a physical chemical system, and presumably under biologic conditions, elements bound in such a manner can be displaced by cations which form similar insoluble compounds, the degree of displacement being dependent upon the solubility and concentration of the displacing cation relative to the adsorbed cation. Complexing agents facilitate the removal process.

Colloids and suspended matter are often irreversibly adsorbed by surfaces. In a biologic system the only safe manner for effective removal of such substances is through the solubilization action of complexing agents. The slight action of sodium citrate in elevating the urinary excretion of Pu and Y is probably due to the complexing action of the citrate ion on the otherwise undiffusible fractions of these radioelements. A large part of the Pu in blood and urine is not ultrafilterable. However, the addition of 0.001M citric acid is followed by a marked increase in the diffusible fraction of Pu, that is, the form in which it is available for excretion through the membranes of the kidney and bowel. A discussion of the action of citrate ion under physiologic conditions, and with particular reference to lead poisoning, is given by Kety.<sup>8</sup> The use of complexing agents such as citrates may be of supplementary value for removing those radioelements with which they form very stable complex ions.

The deposition of the alkaline earths in the bone differs markedly from that of plutonium, yttrium, and zirconium. Thus, radiostrontium is deposited mainly in the mineral structure of the bone while Pu, Y, and Zr are concentrated in the osteoid matrix.<sup>1</sup> It was not expected, therefore, that zirconium citrate would exert an appreciable displacing action on strontium in view of its marked metabolic and chemical differences. In experiments which will be reported at a later date it was found that no significant increases in the urinary or fecal excretion of Sr were observed and neither was its concentration in the liver or skeleton changed as the result of zirconium or sodium citrate administration.

The most effective procedure for hastening the removal of mobile deposits of plutonium or yttrium from the body would be to administer zirconium citrate at least twice daily over an extended period. The sooner treatment is begun and the larger the initial dose, the greater should be the net reduction in body content, particularly in the amount deposited in the skeleton. The effect of oral administration of zirconium citrate is under investigation.

It is hoped that a correlation of the results of these and subsequent metal displacement experiments with the chemical and metabolic properties of the radioelements involved will facilitate the devising of effective procedures for removing radioelements from the body.

## SUMMARY

A study was made of the effect of a single dose of zirconium citrate on the excretion and distribution of plutonium and radioyttrium in rats and a growing dog. It was found that early administration of zirconium citrate to rats increased the excretion of Pu from 1 per cent to 50 per cent and that of Y from 25 per cent to 60 per cent of the injected dose during a twenty four hour period. The amount of Pu and Y deposited in the skeleton was reduced by factors of 6 and 2.6 respectively. No significant changes in the Pu or Y contents of the feces, liver, spleen or kidney were found.

The administration of zirconium citrate to a dog five months and two and one half years after exposure of Pu was followed by a sustained increase in the excretion rate. The extent of the increase was proportional to the dose of zirconium citrate.

A discussion is given of the chemical concepts involved in applying metal displacement principles to the removal of radioactive metals from the body.

The writer wishes to express his gratitude for the technical services of Miss P. Boykin, Miss C. Brown, Mr. Walter Kiseleski, Mrs. T. McFall, Mr. D. Revinson, Mrs. J. Tolmach, and Mr. H. Wallace Jr.

The advice and generous cooperation of Dr. A. M. Bruce, Dr. H. I. Iseco, Dr. M. P. Finkel, Mr. E. R. Russell and Miss M. N. Swift are greatly appreciated.

# THE SIGNIFICANCE OF THE AMINO ACID COMPOSITION OF THE PROTEINS EXCRETED BY THE NEPHROTIC CHILD

ANTHONY A. ALBANES<sup>1</sup>, PH D, VIRGINIA I. DAVIS, B S, EMILIE M. SMITAK,  
AND MARILYN LEIN  
NEW YORK, N. Y.

THE view that the nephrotic syndrome is the result of a general metabolic disorder is not as yet adequately supported by the evidence, but there is no question among clinicians that the problem of managing the disease is a metabolic one<sup>1</sup>. The problem stated in its simplest terms is to achieve a compensatory repletion of proteins lost to the organism by excretion into the urine and abdominal fluid. Although the solution of this problem may or may not in itself correct the primary cause of the disease, it may accomplish a favorable prognosis by mitigating the hazards of the concomitant malnutrition. To realize the magnitude of the cachexia induced by this disease, it is only necessary to recall that on the basis of Rubner's values<sup>2</sup> each gram of protein lost via the urine alone is equivalent to a loss of 5.3 Gm. of body tissue—and a daily output of 25 Gm. of urinary protein is not uncommon in nephrotic children.

In cognizance of this aspect of the disease a variety of proteins and protein products have been empirically assayed orally and parenterally in the therapy of nephrosis with varying degrees of success<sup>3, 4, 5</sup>. These efforts have attempted primarily to replenish protein losses by augmenting protein input over and above the amount which can be given in the form of normal foods. Since a similarity in amino acid patterns of the proteins administered and those lost in the biologic fluids during the course of the disease might reasonably afford a greater measure of compensation than those of dissimilar pattern. We have undertaken to obtain and report data, heretofore lacking, on the amino acid composition of proteins excreted by children afflicted with the nephrotic syndrome. In addition to furnishing a guide as to the types of proteins most suitable for dietotherapeutic treatment, these results disclose (a) that the composition of the urinary proteins varies with the severity of the symptoms, (b) that the composition of the proteins found in the abdominal fluid may or may not simulate that of the proteins occurring simultaneously in the urine, and (c) that only in the improved stages of the disease does the albumin of the urine approximate the albumin of the blood in amino acid composition.

## EXPERIMENTAL

Since we were concerned primarily with determining the total quantity of amino acids lost in the excreted proteins as a whole rather than the variety of protein species

From the Department of Pediatrics, New York University College of Medicine and the Children's Medical Service, Bellevue Hospital.

The work described in this report was supported by grants from the Sheffield Farms Company of National Dairy Products, Inc.

Received for publication Nov. 3, 1948.

it was considered expedient to attempt to fractionate the proteins and to forego the niceties of electrophoretic separation.<sup>7</sup> It seems reasonable to assume that for dietotherapeutic interpretations the over-all amino acid pattern of the urinary proteins irrespective of kind, is the practical criterion. By this token we shall not attempt a detailed classification of the nature of the kidney involvement. Considerable dissimilarity of clinical opinion prevailed in several of the cases reported here regarding the extent of glomerular damage which coexisted with the nephrotic symptoms. Differentiation on the basis of urea clearance could not be made because of the inconsistency of these data. For our purpose the chemical data on the blood and urine provide objective and adequate criteria.

*Isolation and Analysis of Proteins of Nephrotic Patients.*—In principle the techniques described by Heller and co-workers<sup>8</sup> have been employed for the separation of the urinary and abdominal proteins and their experiences on the relation of the nature of protein mixtures excreted and severity of the disease in the adult have been found to apply for the child.

The urine of the patient was collected and pooled for periods which were considered "critical" or "improved" phases by chemical measurements and clinical observations. During critical period (e.g., the period during which marked nephrotic symptoms were present) the albumin:globulin ratio of the urinary proteins was uniformly below 3.00. During the period of improvement (subsiding of nephrotic symptoms, disappearance of edema, etc.) the albumin:globulin ratio was found to be 10.0 or above.

To each daily collection of urine was added an equal volume of saturated ammonium sulfate, and the collections were pooled for each period usually about five days. The clear supernatant liquid was siphoned off into another jar and to this was added 10 per cent of its volume of 50 per cent trichloroacetic acid to precipitate the albumin. The precipitate from the ammonium sulfate treatment (globulin fraction) was washed three times by decantation. The precipitate (albumin) from the trichloroacetic acid treatment was washed three times in the same manner with 5 per cent trichloroacetic acid. After washing the suspended proteins were poured into the middle compartment of a three-chambered electrolytic cell<sup>9</sup> and dialyzed to remove inorganic impurities. After dialysis each specimen was collected in a 250 cc. centrifuge cup and washed by dispersion in water and dried by successive suspension in 50 per cent, 75 per cent and absolute acetone centrifuging and decanting after each washing. The protein was dried overnight in the 50° oven ground to a fine powder, and stored in small tightly stoppered bottles.

In some urines of the improved period a precipitate was obtained after treatment with ammonium sulfate as described which was found not to be globulin but almost pure uric acid. The urines contained albumin.

From the individual protein samples so prepared, 100 mg. portions were removed for moisture and ash determinations, two 25 mg. aliquots were removed for micro Kjeldahl determinations, a 500 mg. portion was hydrolyzed with 10 per cent NaOH for the tryptophane determination, and a 2 Gm. portion was hydrolyzed with 6N HCl in the usual manner for the determination of other amino acids.

The proteins of the abdominal fluids were prepared and analyzed in the same manner as the urinary proteins.

## RESULTS

In Table I are collected the amino acid data on the urinary proteins of four children who had a long history of nephrosis and died of the disease after these studies were done.

Examination of the analytical results discloses that on the basis of amino acid content the urinary albumin and globulin are distinct protein fractions. However, the urinary albumin and globulin from patients Sm and Te which occurred in nearly the same albumin:globulin ratio are somewhat similar in amino acid composition, whereas the protein fractions from patient Dd which were derived from urines of a lower albumin:globulin ratio contain more

arginine,  $\beta$  hydroxy  $\alpha$  amino nitrogen and tryptophane. The possibility that the excretion of different albumins and globulins as indicated by their amino acid composition predominates at different stages of the disease is further indicated by the data obtained by the analyses of the urinary proteins of patient As who passed through an "improved" period before his death. The accord of the amino acid pattern of the urinary albumin and globulin of "critical" periods I and II of this patient and those of patient Dd which were obtained from urines having approximately the same albumin globulin ratios is surprising.

Following critical period I as indicated by chemical studies and clinical observations, the condition of patient As improved either spontaneously or because of the administration of 50 to 60 Gm daily of an enzymatic digest of lactalbumin (Edman, Sheffield). The analyses of the urinary proteins during this "improved" period disclosed the absence of globulin and the presence of an albumin fraction quite different in amino acid composition from the albumin of the patient isolated from the urine of critical period I. The downward shifts in the arginine, phenylalanine, and  $\beta$  hydroxy  $\alpha$  amino nitrogen are the most significant. Subsequently the patient relapsed, into critical period II, despite the continued administration of Edman, and, as noted, the composition of the urinary proteins returned to that of the proteins

of the critical period I. However, during the course of making urine collections for critical period II, a twenty-four hour urine collection was found to form a heavy white precipitate. This was removed by centrifugation and found to consist of almost pure protein, whereas the supernatant urine was free of protein. Solubility tests showed the substance to be insoluble in water, 10 per cent NaCl, and 10 per cent HCl, but readily soluble in 10 per cent NaOH. It could be readily precipitated from the alkaline solution by the addition of 20 per cent trichloroacetic acid or saturated ammonium sulfate. On the basis of these solubility characteristics this protein would appear to be an albuminoid<sup>20</sup>. This single specimen was purified by electrodialysis and the analytical results were listed under critical period III, the collection for critical period II was naturally terminated with the preceding twenty-four hour collection. Subsequently the condition of the patient rapidly became worse so that further twenty-four hour collections could not be made. Fractional collections showed no evidence of this protein. The analyses of this albuminoid showed it to be quite similar to the globulin of critical period II with the exception of the lower isoleucine and higher  $\beta$ -hydroxy  $\alpha$ -amino nitrogen values.

In Table II are collected the data on two patients who recovered from the disease and are at this writing, two years later, alive and well. It is to be noted that the critical period urinary proteins of patient Al which were isolated from urines having an average albumin globulin ratio of 3.3 are not unlike those of Sm and Tc (Table I) which were obtained from urine having albumin globulin ratios of 2.73 and 2.65 respectively. The albumin secured from the urine of this patient on his improvement and that of patient Me (Table II) whose critical period collections were lost are to be compared with

Tryptophane	2.2	3.3	2.1	3.0

the albumin of patient As (Table I) during the improved period. It will be observed that the amino acid patterns of these three different protein specimens are in remarkable coincidence. The arginine, phenylalanine,  $\beta$ -hydroxy- $\alpha$ -amino nitrogen and tryptophane content of these albumin fractions is significantly and uniformly lower than that of the albumin fractions collected during the critical periods. Indeed the amino acid composition of this albumin simulates that of serum albumin. These patients also were given 50 to 60 gm of L-dimlin daily and their recovery may or may not have been influenced by this therapy.

In order to more completely assess the protein losses during nephrosis we also analyzed the ascitic fluid secured by abdominal tapping of two of the patients coincidentally with the designated urine collection periods. Scrutiny of these analytical results (Table III) discloses that the albumin and globulin of the ascitic fluid of Dd which has only one tenth the total protein concentration as the corresponding urine are not only present in a different albumin globulin ratio from that of the urinary proteins (Table I) but also as might be expected from the foregoing findings possess a vastly different amino acid configuration. The ascitic fluid from As which has about one third the protein concentration as the corresponding urine pool contains proteins which on the basis of amino acid composition are quite similar to those of the urine and as might be anticipated, the albumin and globulin ratios of the two fluids are in good accord. These observations suggest that the species of proteins which filter into the abdominal cavity are not necessarily identical with those filtering into the urine. The quantitative and qualitative disparity or similarity of the proteins occurring in these fluids probably reflects the nature and extent of the existing kidney damage.

It is obvious that the validity of the deductions made regarding the similitude or dissimilitude of the proteins described heretofore is seriously limited by the lack of data on the amino acids for which no quantitative measurements were made. This deficiency arose primarily from the lack of adequate chemical methods. However we were able by means of paper chromatograms<sup>1</sup> to ascertain, within the limits of this technique, the general distribution of the other amino acids. Thus it was found that the lysine content of the albumin and globulin preparations from the critical periods of all patients were about the same and both were much higher than the albumin of the improved period. No marked difference in the distribution of all the other amino acids of either the globulin or albumin fractions could be detected.

#### DISCUSSION

It is evident from the results presented here that the dietotherapeutic treatment of nephrosis must take cognizance of the kind and amount of protein lost during the course of the disease. The high proteinuria of the critical period not only involves a greater loss of proteins than the benign period but also a loss of higher quality proteins as indicated by their greater content of essential amino acids. Hence the nutritional stress is qualitatively far greater than the actual quantity of excreted proteins denotes.

TABLE IV COMPARISON OF THE AMINO ACID COMPOSITION OF HUMAN BLOOD PROTEINS, COW'S MILK PROTEINS, AND URINARY PROTEINS OF NEPHROSIS

(All values are given in grams amino acid per 100 Gm. protein)

AMINO ACID	URINARY PROTEINS		HUMAN PLASMA PROTEINS (BRAND <sup>22</sup> )					HUMAN GLOBIN*	CASEIN (AMIGEN*)	LACTALBUMIN (EDAMIN*)
	ALBUMIN	GLOBULIN	ALBUMIN	$\gamma$ GLOBULIN	$\beta$ GLOBULIN	$\alpha$ GLOBULIN	FIBRINOGEN			
Arginine	5.4	5.5	6.2	4.8	6.8	7.7	7.9	3.3	2.4	3.2

\*These amino acid values were obtained in this laboratory by the use of the same methods employed for the analyses of the urinary proteins

On the basis of our evidence, it seems that some suggestions can be made as to the kind of proteins or amino acid mixtures which might be expected to alleviate better the amino acid depletion induced by the disease. Thus, if we compile the average composition of urinary proteins collected during the critical phases of the disease (albumin globulin ratios 1.68 to 3.30) and compare these amino acid values with those of proteins which have been employed in the treatment of nephrosis, a measure of their possible efficacy can be gained (Table IV). It is clear from these data that none of the human blood proteins provide amino acids in the general pattern in which they occur in the urinary proteins<sup>4, 5, 6</sup>. Attention is called to the methionine, isoleucine, and tryptophane deficiencies of plasma albumin, the methionine, cystine, phenylalanine, and isoleucine deficiencies of the globulins, and the cystine and phenylalanine deficiencies of fibrinogen. Human globin is poor in cystine and isoleucine by comparison with urinary albumin and globulin. Turning to the milk proteins we find that casein (Amigen) is lacking in cystine, phenylalanine, and tyrosine,<sup>3</sup> whereas lactalbumin (Edamin) is low only in cystine and phenylalanine. Of course any protein given in large enough quantities will compensate for the urinary protein losses, but this practice involves the administration of large quantities of unnecessary amino acids which the already metabolically embarrassed organism must degrade and thereby inevitably augment the prevailing high blood nonprotein nitrogen beyond the limits of tolerance. In view of these considerations it would seem more reasonable to assay the value of available digests which have been supplemented with pure amino acids to simulate the amino acid configuration of the urinary proteins.

In addition to this practical application, these findings also serve to answer in part the question of the origin of the proteins excreted in nephrosis. A comparison of the amino acid composition of the urinary proteins and the normal blood proteins (Table IV) indicates that neither the urinary albumin or globulin of the critical period could arise respectively from the plasma albumin or any mixture of the plasma globulins. This leads to the surmise

that the hypoproteinemia of nephrosis does not result primarily from a loss of blood proteins into the urine but from the repletion of amino acids to the formation of the aberrant proteins which are excreted into the urine and abdominal cavity

#### SUMMARY

Amino acid analyses of the proteins found in the urine and abdominal cavity of patients suffering from nephrosis reveal that the urinary albumin and globulin have a different amino acid pattern from the plasma albumin and globulin. This finding suggests that the hypoproteinemia of the disease is due to the utilization of amino acids for the formation of the aberrant proteins occurring in the excretory fluids rather than the excretion of normal blood proteins. The further suggestion is made that protein preparations which simulate the amino acid patterns of the urinary proteins be assayed in the dietotherapy of the disease.

We are very gratefully indebted to Dr. George Hussar, Dr. John Birmingham and Dr. Selma C. Snyderman of the Children's Medical Service for the medical care of the patients.

## NUTRITIONAL STATUS AND INFECTION RESPONSE

### II ELECTROPHORETIC CIRCULATING PLASMA PROTEIN, HEMATOLOGIC, HEMATOLOGIC, AND PATHOLOGIC RESPONSES TO MYCOBACTERIUM TUBERCULOSIS (H37RV) INFECTION IN THE PROTEIN DEFICIENT RAT

#### INTRODUCTION

THE concept that malnutrition increases susceptibility or reduces resistance to tuberculosis gained impetus after the World War of 1914 to 1918. Increased mortality in Europe to tuberculosis during that period was ascribed by epidemiologic inference largely to nutritional deficiencies—particularly deprivation of proteins and fats.<sup>1-4</sup> These epidemiologic observations have not been supported by controlled laboratory experiments. An adequate experimental approach however is difficult to achieve for chronic tuberculosis occurring in man is somewhat different from the disease produced in experimental animals.

Since a multiplicity of factors undoubtedly influence the susceptibility, resistance, and course of tuberculosis it seemed desirable to approach experimentally the problem of dietary deficiency in relation to resistance to and course of this disease by using an ordinarily resistant animal species. The albino rat was chosen since its diet could be well evaluated. It has a relatively high resistance to experimental tuberculosis. When appropriately infected by virulent strains of tubercle bacilli granulomatous lesions occur although rats rarely die of the disease. Employment of the rat in the study of problems associated with tuberculosis is not unique.<sup>5-8</sup> Several of these studies were concerned with the influence of nutritional factors upon experimental tuberculosis.<sup>10-14</sup> only two with the effect of protein deficiency.<sup>10, 8</sup> Because of the current interest regarding the relation of protein deficiency to infection response stimulated by Cannon<sup>15, 16</sup> it seemed desirable to review this particular phase of the tuberculosis problem utilizing more recently available techniques. Accordingly controlled studies were done embracing several concomitant phases of physiologic and pathologic responses to tuberculosis infection and protein deficiency—including growth food consumption, the concentration total circulating, and electrophoretic distribution of plasma proteins hematology and hematopoietic variations, and histologic tissue response. Well nourished and chronically protein deficient rats, as well as animals with subsequently superimposed acute severe protein deprivation were studied.

Received for publication Nov. 1, 1948.

## METHODS

In preliminary experiments, consistent infection was obtained and physiologic and pathologic responses were noted. In this experiment, sixty four young, growing, male, Sherman strain rats (60 to 70 grams) were used. These were isolated in individual wire mesh cages and kept in a room maintained at 75° F. After an initial seven day acclimatization period on a basal 18 per cent casein diet,\* the animals were divided into two major diet groups. Thirty one rats were continued on the basal 18 per cent casein diet. Thirty three rats were reduced to an 8 per cent casein diet\*. After two weeks on these control and moderately protein deficient diets, the animals were divided into experimental groups and inoculated as follows:

DIET	INFECTED	GROUP	
		Heat killed organisms	NONINFECTED Diet control no organisms
18% protein level	19	6	6
8% protein level	20	6	7

Infection was accomplished by direct intrajugular injection of 0.05 c.c. of a suspension containing 0.1 mg. of a young culture of virulent, viable, human strain (H37RV) bacilli. A similar suspension of heat killed organisms was injected intrajugularly as an infection and tissue response control procedure. A third group of animals served solely as diet controls. Four weeks (twenty eight days) after infection and six weeks after the experimental diets were begun, approximately half the remaining infected and control animals of each diet group were reduced acutely to a 2 per cent casein level. Blood samples for the various studies were drawn from an appropriate sample of the respective diet groups prior to infection and before groups of animals were sacrificed at fourteen, twenty eight, forty two, and fifty eight days after infection. One milligram of old tuberculin (O.T.) was injected intracutaneously in all rats forty eight hours prior to sacrifice.

\*The experimental diets were isocaloric and similar to those used in previously reported studies.<sup>4</sup> They had the following composition:

DIET COMPOSITION PER 100 GM. RATION

FOOD	ADEQUATE RATION (18% CASEIN)	MODERATELY DEFICIENT RATION (8% CASEIN)	DEFICIENT RATION (2% CASEIN)
Casein	18 Gm	8 Gm	2 Gm
Sucrose	73 Gm	83 Gm	89 Gm
Mazola	5 Gm	5 Gm	5 Gm
Phillips & Harts salts	4 Gm	4 Gm	4 Gm
Cystine	0.2 Gm	0.2 Gm	0.2 Gm
Thiamine Cl	200 γ	200 γ	400 γ
Pyridoxine	200 γ	200 γ	400 γ
Riboflavin	400 γ	400 γ	800 γ
Niacin	25 mg	25 mg	50 mg
Ca pantothenate	15 mg	15 mg	30 mg
Choline Cl	100 mg	100 mg	200 mg
Inositol	100 mg	100 mg	200 mg
Biotin	50 γ	50 γ	100 γ

Halibut oil was fed in 0.1 c.c. amounts biweekly. Water was offered ad libitum. Diets provided 4.1 calories per gram ration. The 18 per cent casein diet afforded 134 to 431 mg. N per twenty-four hours per 100 gram rat; the 8 per cent diet 68 to 177 mg; the 2 per cent diet 15 to 34 milligrams.

†The subculture used was derived from the original strain isolated in 1904.<sup>4</sup> The viability of the subculture was satisfactorily demonstrated by inoculation of five guinea pigs with a thirteen-day subculture grown in a liquid medium.<sup>7</sup> After several animal passages a Dubos media young (seven-day) growth representing a fifth subculture was removed from the media by centrifugation, washed three times with Ringer's solution, and weighed. The organisms were resuspended in Ringer's solution. An even suspension containing 0.1 mg. per 0.05 c.c. was used for injection. A similar heat-killed suspension was prepared by autoclaving. The heat-killed organisms retained morphologic characteristics. In the preliminary experiments bacilli were recovered from infected tissue cultured and subsequently inoculated into guinea pigs producing the typical disease pattern in these susceptible animals.

Hemoglobin (oxyhemoglobin) was determined with the Klett Summerson photoelectric colorimeter (using a 540 m $\mu$  filter). The relative cell volume was calculated from it.<sup>48</sup> Total leucocyte and differential counts were done by the usual methods. Total plasma protein concentration was determined gravimetrically by the copper sulfate method.<sup>49</sup> Blood volume partition studies, using Evans blue dye T 1824 and a modified single sample photoelectric microcolorimetric technique<sup>48</sup> were done concurrently with the above mentioned concentration determinations. Unit circulating protein and hemoglobin values were readily calculated by adjusting total volumes to a unit surface area (milliliters per 100 cm SA).<sup>50</sup>

Sera from the sacrificed animal were pooled by groups for electrophoretic analyses. Electrophoreses were carried out over a 1.0 minute period in a modified Tiselius apparatus, according to the technique of the Department of Physical Chemistry.<sup>51</sup> Owing to poor light transmission of the dyed plasma a 1.0 per cent protein concentration was found more practical than previously used 2 per cent concentrations. No significant variation in pattern composition would be expected to result from this more dilute protein concentration. The 1.5 per cent solution was obtained by dilution with and dialyzation against, sodium diethylbarbiturate buffer of pH 8.6 and 0.1 ionic strength. Mobilities were calculated from the descending boundary patterns of five times enlarged schlieren diagrams. Compositional data represent an average derived from planimetric resolution of both ascending and descending boundary patterns excluding the delta and epsilon boundary anomalies.

Bone marrow imprints<sup>53</sup> were obtained from the distal diaphyseal third of the left femur when the animals were sacrificed. Eight to ten consecutive imprints were made on each of three cover slips. In addition to the usual May-Grünwald-Giesma stains, occasional sections were stained with the Ziehl-Neelsen technique. Cytologic classification and grouping were as previously described.<sup>4</sup>

At specified intervals infected and control animals were killed by ether anesthesia and all viscera grossly examined. The tissues were then fixed in Zenker acetic fixative for twenty-four hours and washed in tap water for a similar period, and paraffin blocks were prepared. Routine sections were made of lungs, tracheobronchial nodes, heart, liver, spleen, kidneys, adrenals, testes, and skin at the site of inoculation with O.T. The intestine, pancreas, and mesenteric nodes of a few animals were sectioned at random. All sections were stained with cosin-methylene blue and where indicated, duplicate sections were stained by the Ziehl-Neelsen technique for tubercle bacilli in tissues.

## RESULTS

### 1 Pathology—

#### a Gross Examination

At autopsy no significant gross changes were noted in the noninfected rats, regardless of dietary status. Several rats died spontaneously of intercurrent infection or trauma incident to cardiac puncture. The latter procedure frequently accounted for focal pulmonary hemorrhage. An occasional intercurrent infection of the lungs obscured gross lesions commonly evident in experimentally infected animals,<sup>54</sup> but did not interfere with the demonstration of *Mycobacterium tuberculosis* in the tissues. Specific gross lesions were consistently demonstrable in lungs and spleen of infected animals. In several control rats, white specks (microscopically identified as lymphoid tissue) dotted the pleural surfaces of the lungs, these nodules usually were not greater than 0.5 mm in diameter. No appreciable pathologic differences existed between control and infected animals at two weeks. However as the postinfection period lengthened smooth, slightly elevated gray-white opaque nodules became conspicuous and progressively larger on the pleural surfaces of the lungs of infected rats. These nodules attained an average diameter of 2 mm eight weeks after infection.

FIG. 1A

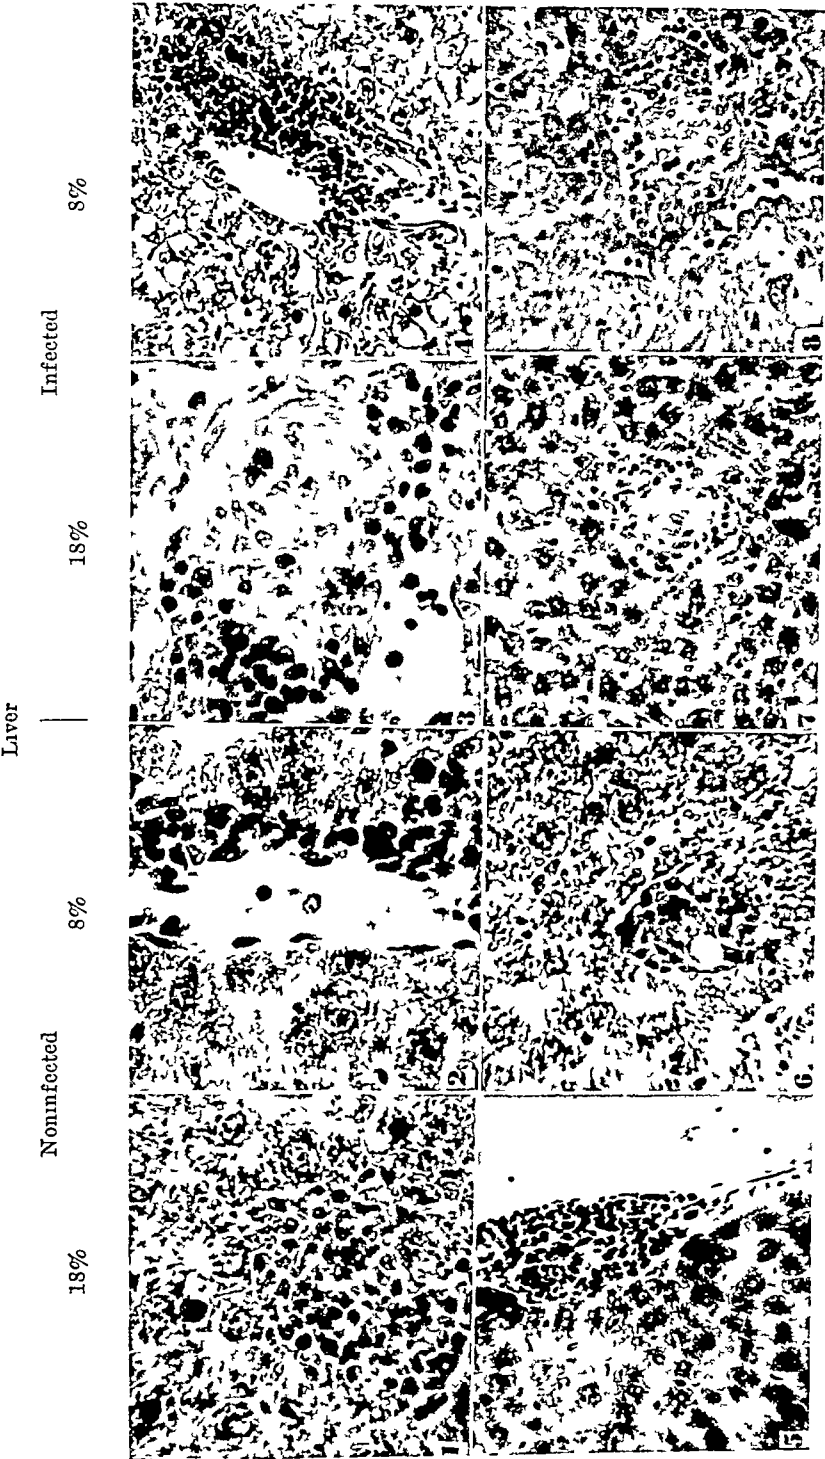

Note. 18% and 18% refer to diet protein levels. weeks refers to weeks postinfection. 6.8 refers to animals reduced acutely to % diet protein levels two weeks prior to sacrifice at six to eight weeks after infection.

#### Spleen

1 (X300) Large germinal center in Malpighian follicle nodules in splenic pulp. No definite marginal zone lymphocyte infiltration. 2 (X60) Follicle architecture distorted by presence of numerous phagocytes. Few lymphocytes at periphery. 3 (X180) Normal node. 4 (X170) Large germinal center in Malpighian follicle. 5 (X390) Small node adjacent to central arteriole. Remainder of pattern of Malpighian follicle unchanged. 6 (X355) Numerous intranuclear nodules. 7 (X510) Inoculated with heat killed bacilli. Dense histiocytic infiltration both within and surrounding Malpighian follicle. 8 (X400) Small node in periphery. 9 (X350) Malpighian follicle. 10 (X400) Splenic nodules. 11 (X400) Splenic nodules. 12 (X400) Splenic nodules. 13 (X170) Increase in lymphocytic component of follicle. 14 (X400) Splenic nodules. 15 (X400) Splenic nodules. 16 (X700) Extra Malpighian node. No central breakdown. Very cellular reaction.

**Summary of Spleen Pathology** Nodules in the spleen produced by *Mycobacterium tuberculosis* were histologically similar to the seen in other organs and were more numerous within the Malpighian follicles. So little exudative cellular reaction was seen in association with these nodules in the spleen that they frequently appeared as foreign bodies completely surrounded by normal splenic tissue. Lesions in the spleen of animals fed diets deficient in protein were not significantly different from those lesions seen in well fed animals. In the spleen of animals fed diets deficient in protein, there was a reduction of lymphoid tissue. In general, however, no constant changes due to protein deficiency were detectable histologically in the spleen.

Liver

Fig 1B

1 (X530) Diet infection control. Focus of round cell infiltration lymphocytes and Kupffer cell derivatives. No nodule formation  
2 (X720) Round cell infiltration at lobule periphery. early hyperchromatism of liver cell nuclei and swelling of cytoplasm due to protein  
deficiency 3 (X630) Nodule with surrounding zone of lymphocytes and Kupfferian derivatives. Liver cells well nourished. Sinusoids wide-  
ly patent 4 (X235) Perivascular lymphoid tissue. No evidence of tuberculous localization. Liver cells show marked protein depletion

5 (X-237) Similar to 1. Adherent to portal vein, no evidence of protein deficiency. 6 (X-470) More advanced protein deficiency showing expansion of sinusoid, swelling of hepatocytes, slight cellular infiltration. 7 (X-480) Similar to 5 with less cellular reaction. No swelling of liver cells. 8 (X-336) Similar to 5 with slight cellular infiltration. 9 (X-10) Similar to 5 with less cellular reaction. Infection control was inoculated with heat killed bacilli. Sinusoidal cellular infiltration. 10 (X-110) Similar to 5 with less cellular reaction. Diet infection control inoculated with heat killed bacilli. No specific cellular infiltration. No histologic evidence of granuloma. 11 (X-530) Earliest liver lesion showing coalescence of epithelial cells and slight cellular infiltration. No evidence of protein deficiency. 12 (X-700) Well developed nodule in sinusoid. No surrounding cellular infiltration. Slight cellular infiltration. 13 (X-10) Similar to 12 with heat killed bacilli. Hypereosinophilic nuclei, double nuclei and cytoplasmic vacuolation indicative of severe protein deficiency. 14 (X-180) Inoculated with heat killed bacilli. Marked rarefaction of liver cells, splintering sinusoids, indicative of severe protein deficiency. Dense circumscribed nodule with slight cellular infiltration. In spite of advanced protein deficiency manifested by swelling of hepatocytes and cytoplasmic vacuolation of liver cells with obliteration of sinusoid and hyperchromatic nuclei no advance in progress of the reaction. Photographs 3 and 4 are demonstrated. 16 (X-5) Similar to photograph 4 except that liver cells show marked protein deficiency.

### Summary of Liver Pathology

The liver shows a histologic evidence of protein deficiency long before other organs and the changes are rather constant. In the acutely deficient (18 to 25 per cent) animals in this series, changes were present in liver cells with obliteration of sinusoids, peripheral displacement and gradual (all appearance of ribonucleic acid granules) perchromatic and often multiple nuclei and an increase in scintillant fat in liver cells. These changes were, pre-ent but not so constant in the less acutely deficient animals.

No significant alteration in character of liver le fons produced by *Mycobacterium tuberculosis* was effected by maintaining animals on diets relatively deficient or extremely deficient in protein

As in the lung numerous active and latent foci of lymphoid tissue are thought to exist in the livers of normal well fed rats,

Lung

Fig. 1C

1 (X310) Nonspecific alveolitis. Many alveolar phagocytes but no nodule formation. A frequent finding in control animals. 2, (X420) Atelectatic lung. Few histiocytes but no specific pattern. 3 (X240) Focus of intra-alveolar nodule formation resulting from coalescence of histiocytes many of which are shown in photograph. 4 (X590) Nodule with early central necrosis but no true caseation.

In infected animals rounding of the normally sharp borders of the spleen resulted from diffuse enlargement to approximately twice normal size at the end of eight weeks of infection. Tiny, poorly defined, pinhead sized nodules projected slightly above the surface, and the entire organ assumed an opaque translucency resembling glazed orange rind.

Varying degrees of involution of the thymus were noted in all animals after pubescence. The skin of the abdomen at the site of tuberculin inoculation showed slight induration and a dry, brown crusting in many of the control as well as infected animals after forty eight hours. No erythema was noted at the periphery of the indurated area in any animal. Systemic reactions due to injection of tuberculin<sup>26, 31, 38</sup> were not observed.

#### *b Microscopic Examination—Noninfected Animals*

A study of the histology of the organs of thirty young control rats revealed several anatomical characteristics which merit brief comment.

**Lymphoid Tissue** Lymphoid tissue was widely distributed throughout the lung parenchyma where it assumed the form of peribronchial and perivascular "collars." Occasionally, in these zones, well developed germinal centers formed large nodules. The tracheobronchial nodes were well developed, in some instances with prominent primary and secondary follicles. The lymphoid tissue of the spleen was characteristically dense, particularly the Malpighian follicles in which large, clearly demarcated secondary follicles were consistently present. In other organs, such as the liver, lymphoid tissue was less conspicuous, usually consisting of aggregates of lymphocytes and macrophages adjacent to the trabeculae.

**Lungs** The lungs of all rats commonly revealed large cells having small, round or oval vesicular nuclei and extremely pale cytoplasm. Frequently, the cytoplasm was identified only by the demarcating cell membrane, occasionally it appeared unusually foamy. These cells were either present in alveolar septa or lying free in alveolar air spaces. In the septa, they appeared closely associated with lymphoid tissue. In the air spaces, they rather closely resembled the alveolar phagocytes, or heart failure cells, often seen in human lungs. These cells are thought to play an important role in the reaction of the rat to infection with *Mycobacterium tuberculosis*.<sup>39</sup>

**Liver** An inconstant, though frequent, degenerative change was noted in the livers of rats subjected to severe dietary protein deficiency. Hepatocellular degeneration was evident in the peripheral areas of the lobules. It was characterized by liver cell swelling, cytoplasmic rarefaction, frequent hyperchromatism of nuclei, and a conspicuous cell membrane. Because of the cellular swelling, the sinusoids in these areas seemed obliterated. Basophilic granules (presumably representing ribonucleic acid<sup>55, 56, 57</sup>) were displaced peripherally in the cytoplasm of less severely involved cells and had disappeared entirely in cells showing advanced swelling and rarefaction. Similar hepatic cell changes have been noted in both dogs and rats as a result of protein deficient diets.<sup>59, 60</sup> In this laboratory, such lesions have subsequently been produced within three days in rats on a protein free diet.<sup>61</sup>

#### *c Microscopic Examination—Infected Animals*

**Lymphoid Tissue** In contrast to the findings of Lange and Simmonds,<sup>19</sup> lesions in the tracheobronchial lymph nodes usually seemed to be uniformly distributed throughout the cortical and medullary portions and consisted of discrete nodules made up of eight to twelve epithelioid cells which had coalesced. As in the lungs, no progression of lesions beyond this stage was observed. Lesions similar to those of the tracheobronchial nodes were found in the spleen. These principally occurred in germinal centers of Malpighian follicles, although frequently epithelioid cell nodules were seen in the red pulp. Lymphocytes were relatively rare adjacent to the lesions. Neither necrosis nor coalescence of nodules was observed.

**Lungs** The smallest tuberculous lesion consisted of a group of three or four epithelioid cells which had coalesced to form a syncytial nodule. These epithelioid cells seemed identical with those described as alveolar phagocytes in many of the control animals (Fig. 1). The coalesced cell nodules usually could not be characterized as typical Langhans' giant cells since the nuclei remained well defined and central. Occasional typical Langhans'

cells were noted. In many instances lesions were regularly disposed beneath the pleura at intervals of 2 to 3 mm, frequently in or near peribronchial or perivascular lymphoid tissue. Most lesions showed a few lymphocytes and macrophages at their margins. Occasionally a ring of lymphocytes surrounded the epithelioid cell nodule. In most instances this arrangement could be seen to result from the multicentric development in lymphatic\* or lymphoid tissue of epithelioid cell nodules which compressed the intervening lymphocytes.

Progression of the lesion from this stage consisted merely of coalescence of the syncytial masses into larger nodules constituting a morue (Fig 1). An occasional epithelioid cell contained a rather pale nucleus and more eosinophilic cytoplasm than was evident in neighboring cells, but frank necrosis was not noted in any lesion. No further tendency toward regression or localization of lesions (e.g. walled off or circumscribed by fibroblastic proliferation) was noted after eight weeks of infection than was evident one week after infection.

**Liver** In the liver similar but relatively fewer lesions than were found in the lungs, tracheobronchial nodes, or spleen were noted. Characteristically the lesions were in or very near the trabeculae and usually consisted of a single epithelioid cell nodule of six to ten cells surrounded by a narrow zone of lymphocytes and a few macrophages. In one rat, larger lesions composed of coalescent nodules were noted (Fig 1).

**Kidneys** Kidney lesions were encountered in two rats. One occurred in the cortex and the other in a renal papilla. Both lesions were similar to those usually found in the lungs and liver and consisted of several coalescent epithelioid cell nodules, each surrounded by a narrow zone of lymphocytes and macrophages.

**Testes** The single lesion found in one testicle was similar to those noted elsewhere.

No lesions were found in the intestine or adrenals. Exudates were present only in the peritoneal cavities of two animals which died spontaneously of intercurrent infection.

**Skin** All animals irrespective of infection or dietary status showed considerable reaction to O.T. injected intracutaneously. Dense round cell infiltration consisting largely of macrophages and lymphocytes occurred in the deeper layers of the dermis and subcutaneous tissues in most rats. Edema and slight hemorrhage were commonly seen in the subcutaneous tissues at the site of injection. Local ulceration of the skin was more consistently present in infected and chronically protein deficient animals than in any other group. A few neutrophils invariably were seen near the base of such ulcerations.

**Organisms** In most lesions tubercle bacilli were found in large numbers (Table I) and could often be seen under low power (Fig 1). Most commonly, organisms were found

within the vacuolated nodules formed by coalescing epithelioid cells. In the lungs, however, they were also frequently encountered in single mononuclear phagocytic cells situated along the margins of the alveolar air spaces. Intracellular, acid fast debris often was present in epithelioid cell nodules or in single alveolar phagocytes when organisms were not readily found.<sup>31</sup> The average incidence of bacilli in tissues examined histologically

Fig. 2—Alterations in body weight and libitum ration consumption and estimated nitrogen and caloric intakes associated with tuberculous infection and diet protein deficiency as compared with noninfected and diet controls

appeared to decrease rather markedly within six to eight weeks after infection was initiated. Organisms seemed most persistent in peribronchial nodes and spleen. Diet differences exerted no striking influence upon the persistence of organisms in tissues (Table I). Rather rapid disappearance or dissolution of bacilli in the rat has been previously noted<sup>20, 22, 29, 33, 37, 39, 40</sup>. Differences in diet have been thought to influence the persistence of lesions or bacilli by some,<sup>26, 30, 34, 37</sup> not by others.<sup>19, 20, 21, 41</sup>

## II Growth —

*Caloric and Nitrogen Consumption* Weight increments of 3 to 5 grams per day on the initial control diets represent an adequate growth rate for this age, sex, and strain rat on this 16 per cent casein diet. Weight gain increment with increasing age was relatively exponential. Rats subjected to somewhat deficient nitrogen intakes (8 per cent casein diets) continued to grow but at a considerably slower rate than did controls. A weight increment of 15 to 2 grams per day followed initiation of the 8 per cent diet and within nine weeks diminished to a -0.2 to 1.0 gram per day increment. Superimposition of severe protein deficiency resulted in a progressively greater weight loss in the previously well nourished animals. Infection resulted in no apparent disturbance of growth rates irrespective of diet.

Total ration consumed (grams per twenty four hours per rat) was somewhat greater at an 18 per cent than it in 8 per cent diet protein level (12 to 18 versus 9 to 15 gram per twenty four hours). The unit caloric intake (per 100 gram rat per twenty four hours) was similar at both levels of protein intake (21 to 45 calories). The unit caloric intake diminished with increasing age. The estimated nitrogen intake ranged from 150 to 300 mg nitrogen per 100 gram rat per twenty four hours in the well nourished and 75 to 130 mg nitrogen per 100 gram rat per twenty four hours in the moderately deficient rats. Rats with superimposed severe (2 per cent protein) deficiency consumed 15 to 30 mg nitrogen per 100 gram rat per twenty four hours. Infection induced no alteration in ad libitum food consumption. The similarity of unit caloric and nitrogen intakes at both diet protein levels suggests that pair fed nutrition control data are not essential in these experiments. (Fig. 2)

## III Blood Studies —

Normal values for hemoglobin, leucocyte and plasma protein concentrations in rats of this age, sex, and strain have been previously reported<sup>4, 5</sup>. Infection per se did not result in significant alterations in the concentrations of these various components (Table II).

*Total Leucocyte and Differential Counts* Total leucocyte counts did not appear to be remarkably altered as a result of either infection or moderate dietary protein deficiency. The control animal counts in general tended to be slightly higher than reported normal values for other rat strains. They were consistent with values ranging from 10 to 20,000 WBC per cubic millimeter noted in rats of the same age, sex, and strain on identical diets reported in a previous experiment<sup>4</sup>. The range of established 'normal' values for rat differential counts is rather large. The slight intergroup variations noted were well within the established range. The data suggest a tendency toward relative polymorphonuclear leucocytosis with correlative lymphopenia in both well nourished and moderately deficient rats within twenty eight postinfection days. This tendency was neither constant nor persistent. Few monocytes were usually observed in peripheral smears. Variations in these elements were negligible. Accordingly, the theory of monocyte lymphocyte response as reflected in the peripheral blood in experimental tuberculosis<sup>6, 7, 8</sup> could not be evaluated.

‡Rats previously maintained on 8 per cent casein diet reduced to two per cent casein at twenty-eight

*Hemoglobin* Hemoglobin concentration values for rats of this age, sex, strain, and diet have been established.<sup>50</sup> Observed values showed no significant variation from "normal" irrespective of dietary and/or infection status. Significant changes in available circulating hemoglobin are frequently masked by lack of apparent change in concentration. This phenomenon has been demonstrated previously in relation to protracted moderate protein deficiency.<sup>65</sup> Comparison of initial (preinfection) and final (forty-two to fifty-eight days later) values of unit circulating blood volume and hemoglobin (Table III) suggests that a significant diminution of both attended protein deficiency irrespective

A suggestive increase of erythroblasts and/or normoblasts also was manifested early by infected animals. These changes in cellularity were reflected in the myeloid erythroid ratios.

In general, differences in hematopoiesis between the diet and infection groups were not striking, but variations in myeloid erythroid ratios seemed more closely related to infection than to dietary status. However, animals with protracted or severe protein deficiency had slightly lower ratios than well nourished animals, regardless of infective status.

*Plasma Proteins.* Severe protein restriction superimposed upon a previously moderate diet protein deficiency resulted in slight diminution in plasma protein concentration (Table II). Estimation of plasma protein concentration, however, affords a poor indication of variation in circulating proteins, particularly in protein deficiency states. Protein deficiency per se is attended by significant decreases in unit circulating proteins<sup>6</sup>. Severe diet protein deficiency imposed upon a previously well nourished rat appeared to result in greater relative depletion of unit circulating protein than that observed when severe protein restriction was imposed upon a moderately protein deficient rat (Table III). Slight, probably significant relative increases in unit circulating proteins were evident in the first few weeks of the postinfection period in infected rats irrespective of dietary status. Subsequently similar changes occurred in contrasting groups, hence the relative influence of diet or infection upon the observed circulating protein depletion cannot be assessed or valid inferences drawn. In general the data suggest that unit circulating proteins were slightly but presumably significantly ( $2 + \sigma$ ) increased in infected animals within the three to four week period following infection.

The electrophoretic distribution of plasma protein components varied with the dietary status. Fairly adequate resolution of the major plasma protein components (albumin, alpha beta plus fibrinogen and gamma globulins) was possible under the conditions of electrophoresis. The precise differentiation of alpha 1 and alpha 2 globulins and of alpha 2 and beta globulins was not always satisfactory in the diluted dye protein solution. Poor demarcation of beta 1 and beta 2 globulins commonly occurred. Beta 2 globulins and fibrinogen were not separated in these analyses. An  $\alpha'$  component<sup>4, 5</sup> with mobility greater than that of albumin was usually apparent. However, assuming six components, gaussian curves were drawn and resolution and proportionate composition of both ascending and descending boundary patterns, excluding the delta and epsilon anomalies, were obtained. In order that the data might be compared with that previously reported in the same strain under rather similar circumstances, extended compositional description was attempted despite the above mentioned limitations. With these reservations the plasma composition of several experimental groups is presented in Table V. The available data, however, permit comparison of the influence of diet and infection at fourteen and twenty eight days after infection was initiated and twenty eight and forty two days after moderate dietary protein depletion was begun.

‡Represents the product of the average unit circulating proteins (Table III) derived from the plasma solved schlieren pattern

§Unit circulating protein (Table III)

As usually noted, protein deficiency was attended by relative decrease in the proportion of plasma albumin. The relative proportions of alpha, beta, and gamma globulins did not appear unusually increased in the well-nourished, infected animals and were similar to observed values in the well-nourished, non-infected group. This observation is in contrast to those reported in tuberculous infection of rabbits<sup>1</sup> and man.<sup>2</sup> However, in the protein-deficient groups, the proportions of alpha-2 and beta globulins seemed increased irrespective of infectious status. Diet deficiency with albumin depletion, commonly associated with the moderately advanced phases of tuberculosis, may account for the reported changes in the globulin fractions, as recently suggested.<sup>3</sup> In accord with this hypothesis, consistent decrease in proportion of albumin in the data of Seibert and co-workers<sup>1, 2</sup> suggests that both animals and patients may have been protein deficient. Constancy of simple serum protein concentration values may be misleading in this regard owing to plasma volume lability and/or alterations in relative proportions of the various components.

Concentrations of the various plasma components in Table V were calculated from the proportionate composition of schlieren patterns and total plasma protein concentrations of the respective pools. Since unit circulating protein data appear to be more reliable than simple concentration measurements as an indicator of plasma protein variation, the total circulating amount of each plasma protein component in the vascular compartment was also calculated and adjusted to unit value. The arbitrary values obtained were dependent upon limitations in techniques of resolution of electrophoretic components, plasma protein concentrations, and mean unit plasma volume determinations. The data, therefore, may be more relative than absolute. The results remain proportional, however, since the errors were largely systematic. Unit circulating plasma protein composition reveals the rather marked albumin depletion attending protein deficiency. With this method of calculation, no significant aberration in any of the unit circulating globulin components was observed in response to tuberculous infection, regardless of diet or degree of albumin depletion.

## COMMENT

The possible relation of tuberculosis to specific nutritional deficiency is attended by considerable practical interest. The chemical, physiologic, immunologic, and clinical attributes of protein have stimulated rather extensive speculation in this regard. Variations in blood or plasma component measurements, particularly plasma proteins associated with this chronic disease would seem to afford information pertaining to effect rather than cause.

The concept of protein deficiency as a primary cause of increased susceptibility or decreased resistance to tuberculosis has arisen by inference largely derived from epidemiologic and favored by clinical experience. The conclusion of Faber is most commonly cited in this regard: "A gross underfeeding with the animal, body building nutritives reduces resistance against tuberculosis."<sup>46</sup> This hypothesis was derived from over all tuberculosis mortality data increments associated with a decrease of from forty two to thirty seven per cent in "animal foodstuff" (protein) composition of a diet affording approximately 2,800 to 3,000 calories during the war years 1914 to 1916. Present concepts of protein nutrition suggest that such a diet be considered reasonably adequate for maintenance of nitrogen equilibrium.<sup>47</sup> The marked variation in host and pathogen response dependent upon species genetic characters, diet factors, and physiologic status in the presence of infection with *Mycobacterium tuberculosis*, not to mention the usual, important, commonly associated socioeconomic considerations, has impeded collection of conclusive experimental data.

In an endeavor to define more closely the possible relation of dietary protein deficiency to inferred alterations in susceptibility to or course of tuberculosis, infection was initiated in the rat under controlled conditions. Several concomitant physiopathologic responses to intravenous inoculation of *Mycobacterium tuberculosis* (H37RV) in rats on adequate dietary protein intakes (nitrogen, 134 to 431 mg N per twenty four hours per 100 gram rat) and moderately deficient protein levels (nitrogen 68 to 177 mg N per twenty four hours per 100 gram rat) were observed and correlated. Since relatively few animals were involved in this particular experiment—thirty nine infected, twelve injected with

heat-killed organisms, and thirteen serving as diet controls—the limited data on biologic material necessitate some degree of statistical inadequacy. Results of this and preliminary experiments manifested reproducible consistency.

Summation of the data would seem to favor the concept that dietary protein deficiency—whether moderate or severe, acute or chronic, superimposed upon a previously adequate or inadequate state of protein nutrition—does not significantly alter the susceptibility, resistance or course of infection with *Mycobacterium tuberculosis* (H37RV) in the young, growing rat under the conditions of this study.

Correlation of these observed phenomena associated with the initiation and course of experimental tuberculosis suggests that a somewhat similar approach to the problem in the human being may yield useful, objective data. Until such data become available clinical inference derived from observations on nonindigenous disease in the malnourished rat must be attended by considerable reservation.

#### SUMMARY

1 Intravenous inoculation of viable *Mycobacterium tuberculosis* resulted in definite granulomatous lesions in lymphoid tissue, lungs, and liver, characterized by coalesced epithelioid cell nodules, usually with persistent nuclei and ringed by lymphocytes and few macrophages. Necrosis was not observed.

2 The lesions attained maximal development within four weeks after infection. Recognizable organisms had largely disappeared within eight weeks.

3 No significant difference in the form, incidence, or duration of the specific lesion was observed between well-nourished, moderately, or severely protein deficient animals. No deaths attributable to the infection per se were noted in the forty-two or fifty-eight day postinfection period.

4 Changes in total white blood cells, hemoglobin and plasma protein concentrations as well as in circulating hemoglobin and plasma protein, were consistent with those previously observed in protein-deficient animals. No significant variation in the measurements attended infection per se.

5 Bone marrow studies suggested equivocal changes of myeloid-erythroid ratio in infected animals.

6 Electrophoretic analyses of the circulating plasma proteins revealed apparent increases in the alpha and beta globulin components of the simple areal pattern. No such variation was evident when unit circulating quantities of plasma components were estimated. No specific plasma protein changes resulted from infection per se.

7 Under the conditions of this study, dietary protein deficiency did not appear to alter the susceptibility, resistance, course, or physiologic response of the young rat to experimental tuberculosis.

We are indebted to Miss Campbell of the Department of Bacteriology of Harvard Medical School for the subculture of H37RV used, to Dr. E. J. Cohn and Dr. J. L. Oncley for making the Tiselius apparatus available to us, and to Dr. S. B. Wolbach and Dr. S. Farber for reviewing several typical sections. Their interpretation of the slides was consistent with the observations in this paper.

We wish to thank Dr J F Fuders and Dr C A Jancuwy for their review and criticisms of the manuscript.

We are indebted to Sheldahl Farm Company Inc New York N Y Corn Industries Research Foundation New York N Y and Merck & Co Inc Rahway N J for generous supplies of materials used in the studies.

TABLE V ELECTROPHORETIC VARIATIONS IN PLASMA

GROUP	NUMBER OF ANI MALS	TOTAL PLASMA PROTEIN CONCENTRATION (GM %)	PER CENT PLASMA COMPOSITION *						
			“f”	ALBU MIN	$\alpha_1$	$\alpha$	$\beta_1$	$\beta_2 + \phi$	$\gamma$
18% control <sup>1</sup>	3	6.85	12	48.2	14.0	7.4	6.3	17.2	5.6
18% infected <sup>2</sup>	4	7.44	18	55.6	11.0	5.8	5.2	15.1	5.5
8% control <sup>1</sup>	3	5.68	25	36.6	12.9	12.1	7.1	20.5	8.3
8% infected <sup>2</sup>	5	5.84	28	42.8	12.6	9.3	5.8	21.6	5.1
8% infected <sup>1</sup>	5	5.68	14	44.4	14.2	8.9	5.5	18.2	7.9

<sup>1</sup> Twenty-eight days after infection initiated forty-two days after protein depletion began in 8 per

<sup>2</sup> Fourteen days after infection initiated twenty-eight days after protein depletion began in 8 per cent

The unit circulating protein composition data in parentheses represent values obtained in another son with the 18 per cent infected rats of this experiment since similar unit circulating protein values were trol group of this experiment remains unexplained

\*Somewhat arbitrary values derived from relative areal resolution and representing average per cent

†Derived from the product of the plasma protein concentration of the pool and the per cent areal com

‡Represents the product of the average unit circulating proteins (Table III) derived from the plasma solved schlieren pattern

§Unit circulating protein (Table III)

As usually noted, protein deficiency was attended by relative decrease in the proportion of plasma albumin. The relative proportions of alpha, beta, and gamma globulins did not appear unusually increased in the well-nourished, infected animals and were similar to observed values in the well-nourished, non-infected group. This observation is in contrast to those reported in tuberculous infection of rabbits<sup>1</sup> and man.<sup>2</sup> However, in the protein-deficient groups, the proportions of alpha-2 and beta globulins seemed increased irrespective of infectious status. Diet deficiency with albumin depletion, commonly associated with the moderately advanced phases of tuberculosis, may account for the reported changes in the globulin fractions, as recently suggested.<sup>3</sup> In accord with this hypothesis, consistent decrease in proportion of albumin in the data of Seibert and co-workers<sup>1, 2</sup> suggests that both animals and patients may have been protein deficient. Constancy of simple serum protein concentration values may be misleading in this regard owing to plasma volume lability and/or alterations in relative proportions of the various components.

Concentrations of the various plasma components in Table V were calculated from the proportionate composition of schlieren patterns and total plasma protein concentrations of the respective pools. Since unit circulating protein data appear to be more reliable than simple concentration measurements as an indicator of plasma protein variation, the total circulating amount of each plasma protein component in the vascular compartment was also calculated and adjusted to unit value. The arbitrary values obtained were dependent upon limitations in techniques of resolution of electrophoretic components, plasma protein concentrations, and mean unit plasma volume determinations. The data, therefore, may be more relative than absolute. The results remain proportional, however, since the errors were largely systematic. Unit circulating plasma protein composition reveals the rather marked albumin depletion attending protein deficiency. With this method of calculation, no significant aberration in any of the unit circulating globulin components was observed in response to tuberculous infection, regardless of diet or degree of albumin depletion.

\* No growth in 0.5 µg per cubic centimeter of streptomycin.  
 0.5 1 5 etc indicate the last tube in which there was growth in micrograms per cubic centimeter.  
 Growth in 10 µg or more indicates a resistant strain.

tubercle bacilli grown in Dubos liquid media into 5 c c amounts of the same medium containing an increasing number of micrograms of streptomycin per cubic centimeter, i e, 0.5, 1, 2.5, 5, 10, 15, 31, 62, 125, 250, 500, 1,000. A control tube sans streptomycin was added to each test.

The cultures were examined after fourteen days of incubation to determine the concentration of streptomycin in which growth appeared. At this time the control tube showed maximum (four plus) growth.\*

**Blood Levels**—Streptomycin blood levels were determined by the method of Pulaski and Spinz<sup>6</sup>. (A) A six-hour growth of *Klebsiella pneumoniae* in F D A broth (single strength) was diluted 1 to 50 in double strength F D A. One cubic centimeter was then added to 1 c c of serial saline dilutions of the patient's serum to give a total of 2 c c and a final concentration of 1/2 to 1/64 of the serum. (B) As a control, 0.1 c c of a stock solution containing 320 µg per cubic centimeter of streptomycin was added to 0.9 c c of pooled normal sera. This was serially diluted with 0.5 c c amounts of sterile saline to give concentrations of 32 to 1 µg per cubic centimeter. Five-tenths cubic centimeter of the culture of *K. pneumoniae* diluted 1 to 50 was then added making final dilutions of 16 to 0.5 µg per cubic centimeter in a volume of 1 cubic centimeter. (C) After overnight incubation at 37° C the inhibition was determined by noting the last tube (in A and B) in which there was no growth and dividing the control (B) in micrograms per cubic centimeter by the dilution (A) to give the number of micrograms of streptomycin in 1 c c of patient's serum.

## RESULTS

**Resistance in the 1 Gram Group**—Table I shows the highest concentration of streptomycin in which the particular strain of tubercle bacillus grew and the number of days of therapy after which the organisms developed resistance to the antibiotic. Growth in 10 µg was the criterion used to indicate streptomycin resistance.

TABLE II SUMMARY OF TABLE I, NUMBER AND PER CENT OF PATIENTS BECOMING RESISTANT AT INTERVALS DURING THERAPY

DAYS	TOTAL PA TIENTS	TOTAL TESTED	TOTAL INDI CATED†	SENSITIVE		RESISTANT		PER CENT RESIS TANT
				TESTED	INDI CATED†	TESTED	INDI CATED†

120	19	19	—	10	—	9	—	48

\*The 120 day total is included in the 100 to 120 day group.

†By indicated is meant the streptomycin resistance which would in all probability result had cultures been obtained and resistances determined i e. in Table I Patient 28 would be considered resistant from ninety days onward for Patient 2 after seventy days there would be no indication for Patient 6 there would be no indication between forty and eighty days and would be 1,000 after ninety days. It should be noted that a few cases have been reported in which cultures have been found to revert from resistant to sensitive.<sup>1-5</sup> However in well over 500 sensitivity titrations from cultures on ninety-six patients we failed to find a single instance of decreased resistance of any significance.

\*A comparison was made between streptomycin resistance readings obtained with the media described and the Tween-albumin medium for submerged-dispersed growth subsequently described by Dubos and Middlebrook.<sup>3</sup> In a total of one hundred duplicate tests there was complete agreement in eighty-eight cases. Of the twelve remaining titrations ten showed higher growth in the newer medium and two in the older. However in only one instance would a strain of tubercle bacillus have been considered sensitive in one media and resistant in the other.

It may be observed from Table I as summarized in Table II, that none of the thirty two strains tested before therapy was resistant to 25  $\mu$ g per cubic centimeter of streptomycin. At the end of thirty days of treatment, resistance was still absent in all of thirty patients. However, at the end of sixty days, 13 per cent of twenty four patients had developed resistance. At ninety days 29 per cent of twenty eight patients and at 100 to 120 days, 45 per cent of thirty one patients had become resistant to streptomycin.

*Resistance in the 1.8 to 2.4 Gm Group*—Previous to the inauguration of the 1 Gm protocol six patients had been treated with 1.8 to 2.4 Gm of streptomycin daily. Tests of these strains after 100 to 120 days of therapy showed that 83 per cent had become resistant to 10  $\mu$ g per cubic centimeter. 17 per cent remaining sensitive.

TABLE III POSTSTREPTOMYCIN RESISTANCE 1.8 TO 2.4 GM DATA

PATIENT	DAYS OF TREATMENT	RESISTANCE AT END OF THERAPY ( $\mu$ g/cc)	POSTSTREPTOMYCIN (MO)

118A Second course of treatment for Patient 118

Patients 104, 113 and 118A are cases from Halloran Hospital. All others were transferred to this hospital after completion of streptomycin therapy.

Resistances in micrograms per cubic centimeter. Growth in 10  $\mu$ g per cubic centimeter indicates resistant strain.

A number of patients under the 1.8 to 2.4 Gm treatment (on whom no previous sensitivities had been performed) were transferred to Halloran Hospital after therapy had been completed. Table III indicates the results of post streptomycin resistance tests on thirteen of these transferred patients and three of our own (Patients 104, 113, 118A). It is of interest to note that two patients in this group (104 and 113) as well as two in the 1 Gm group (9 and 16) became considerably more resistant to streptomycin after the completion of therapy.\*

\*These sensitivities were checked and rechecked.

*Serum Levels*—Table IV indicates the range and average level of streptomycin in micrograms per cubic centimeter detected in the serum of the treated patients after thirty days or more of therapy. It may be seen that the average serum level dropped rapidly from 33  $\mu$ g at two hours to 8.6 at eight and then tapered off to 1.7  $\mu$ g at twelve hours.

TABLE IV STREPTOMYCIN SERUM LEVEL IN PATIENTS RECEIVING 1 GRAM (0.5  $\times$  2) DAILY\*

\*Levels taken after thirty days of therapy.

## DISCUSSION

One of the greatest problems in the streptomycin therapy of tuberculosis is the varying rate of time necessary for the tubercle bacillus to become resistant to this antibiotic. In an effort to combat this difficulty and the effects of toxicity, many variations in the amount of streptomycin, the number of daily injections, and the duration of therapy have been tried, both by the Veterans Administration and other investigators.

TABLE V

INVESTIGATOR	GM PFT DAY	DAYS OF TREATMENT	NUMBER OF CASES	NUMBER SPASITIVE	NUMBER RESISTANT	PER CENT RESISTANT	CONSIDERED RESISTANT IF NOT INHIBITED BY
Muschenheim <sup>7</sup>	3	75-120	17	1	16	94.0	500 $\mu$ g/c c
	1	42	12	10	1	9.0	500 $\mu$ g/c c
McDermott <sup>8</sup>	?	90-100	20	1	19	95.0	500 $\mu$ g/c c
VA <sup>9</sup>	1.8-2	60-120	62	23	39	63.0	20 $\mu$ g/c c
Fisher <sup>4</sup>	1.8	120	20	9	11	55.0	10 $\mu$ g/c c
VA <sup>10</sup>	1.8-2	120	88	19	69	78.0	10 $\mu$ g/c c
		60-90				64.0	10 $\mu$ g/c c
VA <sup>11</sup>	1	90	17			61.0	10 $\mu$ g/c c
		120	17			76.0	10 $\mu$ g/c c
VA <sup>13</sup>	1	61-90	115			43.5	10 $\mu$ g/c c
		91-120	117			62.4	10 $\mu$ g/c c

Table V illustrates some of the results of other investigators. It will be observed that the Veterans Administration<sup>10</sup> obtained 78 per cent resistant strains after 120 days of 1.8 to 2 Gm of streptomycin daily. On the other hand, a regime of 1 Gm for forty-two days<sup>7</sup> is reported to have resulted in 9 per cent resistant organisms at the completion of therapy. Other reports on the 1 Gm dose<sup>11</sup> showed 61 per cent resistant strains at ninety days and 76 per cent at 120 days. The most recent Veterans Administration<sup>13</sup> results indicate 43.5 per cent of 115 patients resistant sixty-one to ninety days after the beginning of treatment with 1 Gm daily.

Halloran Hospital was on the 1 Gm 120 day protocol, and the work done here suggests that somewhat less streptomycin resistance had been obtained

than was observed by other laboratories. The 13 per cent found resistant at the end of sixty days and the 29 per cent at ninety days might have a significant bearing on streptomycin therapy if corroborated on a much larger scale.

It has been our observation and that of others<sup>8</sup> that there is an apparent correlation between the appearance of resistance *in vitro* and progression of tuberculous infections. In the ideal situation, therapy would be continued as long as possible without producing drug fastness. Reduction in dosage and duration of treatment has been tried. On the other hand, there is some evidence to show that intermittent injections or short series of injections<sup>4</sup> may prove to give the best effect, especially as it has not been demonstrated that a high blood level of streptomycin must be maintained<sup>18, 19, 23</sup> as is the case in sulfa therapy.

*Resistance Acquired During Therapy*—During therapy the naturally resistant variants of the patient's tubercle bacilli<sup>1</sup> survive and multiply thereby slowly increasing their relative proportion in the strain. In addition to selection, it seems probable that mutation in the direction of organisms with greater resistance to streptomycin also takes place<sup>24</sup> otherwise it would be difficult to explain the development of increased resistance beyond that demonstrated *in vitro* by a few colonies of the strain prior to therapy. If mutation does take place it must be due to the action of the streptomycin as the drug is the only new factor in the treatment of the patient.

*Resistance Acquired Post Therapy*—It is not without significance that in four patients (Patients 9 and 16 in Table I and 104 and 113 in Table III) of a total of twenty-one in whom pre- and poststreptomycin resistances were determined the tubercle bacilli became considerably more resistant after the completion of treatment. In the light of these instances perhaps it would be advisable to wait for a number of months post therapy before final decision is made regarding the degree of resistance attained by the particular strains.

*Streptomycin Assay*—The wide range in the number of micrograms of streptomycin detected in the patient's serum after given intervals of time (16 to 64 µg, at two hours Table IV), may be accounted for by the fact that the assay method used permits determinations no closer than multiples of 4 µg (i.e., 0, 4, 8, 16, 32, 64) and also that 0.5 Gm of streptomycin was administered twice daily to all patients regardless of body weight.

*Sputum Conversion*—The absence of tubercle bacilli in smears and concentrates is one of the standards set by the National Tuberculosis Association

TABLE VI SPUTUM CONVERSION IN STREPTOMYCIN TREATED PATIENTS

INVESTIGATOR	GM / DAY	NUMBER OF DAYS	NUMBER OF CASES	CONVERSIONS		CRITERIA
				NUMBER	%	
Alto	18	120	190	8	43	69 by culture 13 by smear
Oleens	18	120	21	14	66	Culture and smear
	10	120	7	3	43	Culture and smear
San Fernando <sup>14</sup>	20	120	109	72	66	36 culture 34 smears
Williams	20	90	3	17	71	?
Hinschaw <sup>18</sup>	13	60 180	28	13	46	Culture or guinea pig

Also had 60 per cent conversions in the 1 Gm group

for the classification of a patient as "apparently arrested." The disappearance of tubercle bacilli in previously positive secretions suggests that the process has become arrested. However, there is still much confusion in the literature concerning the standards for sputum conversion.

Table VI is a compilation of the results obtained by various investigators. The criteria for conversion ranged from a stained smear to guinea pig inoculation, and the per cent of conversion from 43 to 74. The Veterans Administration<sup>17</sup> has taken a step toward clearing this situation in deciding that cultures must be negative for three successive months before classification as a sputum conversion.

On the basis of smears and concentrates, 41 per cent of the thirty-nine patients reported in this study would be classified as "apparently arrested." However, only three (8 per cent) patients could qualify as conversions by the criteria of the Veterans Administration (Patients 12, 18, and 38 in Table I).

Patient 12 was negative on three monthly cultures obtained post therapy, although the sputum did show Gaffky counts of IV, II, and III on those concentrates. This may be due to the fact that the organisms were not viable during this period.

During the early period of therapy the sputum of Patient 18 was a Gaffky VII. After forty-five days of treatment both smear and culture became negative and continued so for more than three months.

Patient 38 at the start of treatment showed a negative smear with a positive culture. After fifty days of streptomycin both were negative and remained so for the required period of time.

#### CONCLUSIONS

1 The resistance to streptomycin developed by the tubercle bacillus in secretions of thirty-nine patients with pulmonary tuberculosis has been reported.

2 A regime of 1 Gm. of streptomycin daily in two doses twelve hours apart induced no resistant strains at the end of thirty days of therapy. After sixty days, 13 per cent were resistant, after ninety days, 29 per cent and after 120 days, 45 per cent.

3 In four patients (19 per cent of those tested) resistance greatly increased after the cessation of streptomycin treatment. It would therefore seem advisable to postpone final decision on the number of strains which become resistant, as a result of a streptomycin regime, until a number of months after the completion of therapy.

Grateful acknowledgement is made to Dr. Philip Schram for his interest, assistance, and advice in this work.

# BLOOD AND CEREBROSPINAL FLUID CONCENTRATIONS OF AUREOMYCIN AFTER ORAL AND INTRAMUSCULAR ADMINISTRATION

MARK H. LEPPER, M.D., HARRY F. DOWLING, M.D., ROBERT L. BRICKHOUSE, M.D.  
AND ESTON R. CALDWELL, JR., M.D.  
WASHINGTON, D. C.

AUREOMYCIN\* is a recently developed antibiotic derived from *Streptomyces aureofaciens*. It has a wide antimicrobial spectrum both in vitro and in animals. Early trials in various human infections have yielded promising results. It seemed important, therefore, to determine the size of the doses and the intervals between administration which were necessary to maintain demonstrable concentrations of aureomycin in the blood. The results of such a study are reported in the present paper.

## METHOD

Since it was soon found<sup>1</sup> that aureomycin was inactivated too rapidly in vitro to determine bacteriostatic concentrations by a twenty-four hour serial dilution method analogous to the one commonly used to determine penicillin concentrations, a modification of the procedure of Dornbush<sup>2</sup> was adopted. Tryptose phosphate broth was serially diluted by halves in the usual manner with *Bacillus cereus*† as the test organism and the results were read after four hours of incubation at 37° C in a water bath.

The antibiotic was administered to patients orally or intramuscularly in doses shown in Table I. Many patients received only a single dose, whereas others who were being treated for an infection had blood drawn after the first dose and at some later date (Table I).

## RESULTS

Three different dosage regimens were investigated in detail: 100 mg administered intramuscularly, and 300 and 700 mg given by mouth. When 10 mg per kilogram were given to a child, we considered it in the same category as 700 mg in an adult.

When the antibiotic was given orally, the highest concentrations were obtained in the majority of individual patients at the third hour and in a few at the sixth hour, particularly when the larger dose was employed. In only one patient was the concentration highest at the first hour. A detectable concentration of aureomycin was present at the eighth hour in all the samples of blood taken at that time. Aureomycin could be detected in twenty-six of the thirty-two specimens collected twelve hours after administration of a single dose, in four of the twelve specimens obtained eighteen hours after administration, and in eight of the thirty specimens collected at twenty-four hours. In general, the concentrations obtained from a dose of 700 mg orally were higher than those

From the George Washington University Medical Division, Gallinger Municipal Hospital and the Department of Medicine, George Washington University.

Received for publication Sept. 23, 1948.

# MEAN BLOOD CONCENTRATIONS OF AUREOMYCIN IN PATIENTS RECEIVING VARIOUS DOSES BY ORAL AND INTRAMUSCULAR ROUTES

Fig 1

obtained when 300 mg were given by the same route. This is shown graphically in Fig 1, where the mean blood concentrations are plotted against time. When 100 mg were administered intramuscularly, the situation was somewhat altered. One third of the patients showed the highest concentration at the first hour, one third at the third hour, and in one third the first and third hour levels were the same. In all patients the concentration had decreased by the sixth hour. The mean curve (Fig 1) contrasts these differences sharply with those obtained after oral medication.

There are too few patients who received higher doses intramuscularly to reach any conclusions, but it appears that the concentrations were maintained for a longer period of time but were not appreciably higher than when 100 mg were given.

In the case of some of the patients who were treated over a period of several days, initial levels were determined after the first dose and these were repeated after several days. When the drug was administered at six-hour intervals, the blood concentration was essentially the same for each individual patient, indicating that no appreciable amount of piling up occurred. On the other hand, when the interval was shortened to three hours, the levels were somewhat higher and the two patients whose blood was tested at various intervals after the start of treatment showed higher levels after several days of treatment.

Cerebrospinal fluid concentrations were measured on twelve occasions in nine patients, as shown in Table II. It seems likely that the penetration of the

antibiotic into the cerebrospinal fluid is a function both of duration of treatment and height of the blood aureomycin concentration. In the one patient with meningitis who was tested, the presence of meningeal inflammation did not seem to facilitate the passage of the antibiotic.

\*Patient had meningitis

In one patient it was possible to collect two-hour fractional urines over the first six hours following administration of 1,000 mg. by mouth. As can be seen (Table I), about 10 per cent of the material was recovered in the urine during that period, and the urinary concentrations were quite high, being about 100 times that of the blood, or approximately what one would expect in the case of a glomerular filtrate which was not reabsorbed by the tubules.

In one patient it was possible to obtain a measure of activity of the breast milk three days after starting treatment, at a time when the blood concentration was 2.0 micrograms per cubic centimeter. No antibiotic was demonstrated.

#### DISCUSSION

While this study indicates that oral doses of 5 to 10 mg. per kilogram of body weight at six-hour intervals are sufficient to assure measurable amounts of aureomycin consistently in the blood, the optimal dosage schedule still needs to be worked out. From our data it would appear that oral administration at shorter intervals than six hours may increase the height of the level, while if a six-hour interval is maintained there is no piling up. On the other hand, if low continuous levels are desired, larger doses at longer intervals should maintain these with a minimum of disturbance to the patient. Our data suggest that the same is probably true for intramuscular administration and that large doses by this route at fairly short intervals will possibly give the highest concentrations. This has been impractical however, since even with the use of procaine as a diluent there is still too much pain following injection for routine use. Since the antibiotic is so scarce, we have not evaluated the value of a high initial dose (4 to 6 Gm.), but such a procedure may aid in reaching higher concentrations more rapidly.

A second problem remains as to what the therapeutic significance of such levels are. Some information is available which indicates that the effective blood concentration depends on the etiologic organism and that in some diseases the levels demonstrated in this paper are adequate, whereas in others they have

been insufficient. Thus the two patients with Rocky Mountain spotted fever seemed to make an excellent response to therapy, as did the two patients with pneumococcal infections. The abscess caused by *A. aerogenes* healed rapidly, but the patient with endocarditis did not respond to treatment. Moreover, none of the four patients with typhoid had what could be called a response to therapy. It would appear, therefore, that for treatment of certain infections, concentrations in the neighborhood of 0.1 to 2.0  $\mu\text{g}$  per cubic centimeter may be enough, whereas in other infections larger doses at shorter intervals will have to be tried. The good response of five other patients with Rocky Mountain spotted fever and two with pneumococcal pneumonia on whom levels were not obtained but who received equivalent dosage bears out this impression.

The data on the spinal fluid thus far obtained indicate that there is some likelihood of obtaining therapeutic concentrations in this fluid by oral or parenteral administration. That the one patient with pneumococcal meningitis whom we have treated recovered with the use of aureomycin administered by the oral route only is of importance in this regard. Details of the clinical use of this antibiotic will be reported subsequently.

#### SUMMARY AND CONCLUSIONS

1 Blood, cerebrospinal fluid, urine and milk concentrations have been measured following the administration of aureomycin orally and intramuscularly in doses of 100 to 1,000 mg in adults and equivalent amounts in children. In general the higher doses administered by either route tended to prolong the duration of demonstrable activity in the blood and to a lesser extent to increase the peak concentration.

2 Aureomycin was detected in the cerebrospinal fluid of six out of nine patients. Its concentration seemed to depend on the height and duration of the blood concentration.

3 In one patient no aureomycin was found in the milk even with a high blood concentration.

4 The drug is recoverable rather rapidly in the urine where it is found in high concentrations.

5 It is suggested that to maintain lower concentrations, large doses orally at longer intervals seem most convenient and that to obtain high concentrations shortening the interval should be effective. It is possible that a high initial dose (4 to 6 Gm) may allow higher concentrations to be reached and maintained.

6 Blood concentrations obtainable with doses of 10 mg per kilogram by mouth every six hours appear adequate for treatment of Rocky Mountain spotted fever and pneumococcal pneumonia.

We wish to thank Mrs. Joan R. Brovhill and Miss Myrtle I. Meyer for technical assistance.

# THE ACTION OF THEPHORIN UPON HISTAMINE-INDUCED GASTRIC SECRETION IN DOGS AND ON GASTRIC ULCER FORMATION IN RATS

G. LEHMANN, M.D.,† AND PAUL L. STEFKO  
NUTLEY, N. J.

CONSIDERABLE disagreement exists as to the effect of antihistaminic substances upon histamine-induced gastric secretion. This is true both of the original compounds of this type thymoxy ethyl diethylamine (929 F)<sup>1, 3</sup> and N-phenyl-N, N,N'-triethylethylenediamine (1571 F)<sup>2, 4</sup> and of the more recently developed antihistamines Benadryl<sup>4</sup> and Pyribenzamine.<sup>5</sup> The majority of investigators failed to observe any significant decrease of histamine-induced gastric secretion in dogs pretreated with antihistamines. Similar observations have been made in man.<sup>8, 10</sup> Some clinical investigators reported an increase of gastric acidity after the administration of antihistamine compounds.<sup>11, 12</sup>

The reports concerning the influence of antihistamines upon the occurrence of histamine-induced gastric ulcers in experimental animals<sup>6, 13, 15</sup> are rather unanimous. The histamine antagonists did not prevent ulcer formation.

Since Thephorin\* (2-methyl-9-phenyl-2,3,4,9-tetrahydro-1-pyridindene), which is a potent antihistamine<sup>16, 17</sup> synthesized in the Roche Research Laboratories by Dr. W. Wenner and Dr. J. T. Platt, differs both structurally and pharmacologically<sup>18</sup> from other histamine antagonists, it seemed desirable to study its influence upon gastric secretion and ulcer formation produced by histamine and on "spontaneous" ulcer formation.

*I The Effect of Thephorin on Gastric Secretion*—Gastric secretion was studied in three trained, unanesthetized, female dogs weighing from 10 to 12 kilograms with denervated gastric pouches (Heidenhain). Two series of experiments were carried out.

In the first series the animals received subcutaneously 0.1 mg. per kilogram histamine phosphate thirty minutes after the subcutaneous injection of 20 mg. per kilogram Thephorin. In a second series of experiments, 0.025 mg. per kilogram of histamine phosphate was used to stimulate gastric secretion. In addition, control experiments in which the administration of Thephorin was omitted were carried out with the same doses of histamine phosphate. Each type of experiment was done in triplicate in each dog at least three days apart. Thus a total of thirty-six experiments have been performed in three dogs. The animals had been starved twenty hours prior to the experiment.

Gastric juice was collected for one hour at ten-minute intervals. Both volume and free hydrochloric acid were determined, the latter by titration using Sahli's reagent, a mixture of equal parts of 48 per cent KI and 8 per cent KIO<sub>3</sub>. In addition, the pH of each sample was measured by means of a Beckman pH

From the Pharmacology Department, Hoffmann-La Roche, Inc.

Received for publication Oct. 14, 1948.

†Deceased.

Fig. 1—Effect of Thephorin on histamine induced gastric secretion in dogs. Abscissa, time in minutes. Ordinate, solid columns, cubic centimeters of gastric juice; solid plus hatched columns, milligrams of free hydrochloric acid.

meter. The average values for each dog, from three experiments with two histamine doses each are presented in Table I which demonstrates that only the volume of secretion was reduced to a significant degree by Thephorin whereas the hydrogen ion concentration remained practically unaltered. The average decrease in volume and consequently in the quantity of free hydrochloric acid amounted to about 30 per cent regardless of the dose of histamine used. The average amount of hydrochloric acid produced by 0.025 mg per kilogram histamine phosphate is almost identical with that after 0.1 mg per kilogram histamine phosphate in the presence of 20 mg per kilogram Thephorin; thus 75 per cent of histamine has been rendered ineffective by Thephorin.

*II The Effect of Thephorin on Histamine Induced Ulcer in Rats*—Thirty Sprague Dawley male rats weighing from 280 to 340 grams (average weight 310 grams) received daily by intramuscular injection 60 mg histamine phosphate in a mixture of beeswax and mineral oil, prepared according to Varco and co-workers<sup>19</sup>. These rats had been used for a vitamin A assay several months prior to this experiment and were on a normal Rockland mouse diet. Of thirty animals used in this experiment ten received subcutaneously 20 mg per kilogram Thephorin and ten received 10 mg per kilogram atropine five hours after the histamine injection. The remaining ten rats served as controls. The treatment of the surviving animals was carried on for thirty days after which time they were killed and autopsied.

From Table II it is seen that Thephorin has a definite prophylactic effect against histamine induced ulcer formation. Eight control animals and nine of the animals pretreated with atropine died from perforated ulcer during the

Atropine 10 mg/kg	10	3	3	2	2	1	1.3+	2

later the animals were autopsied the surviving ones being killed by ether inhalation. The degree of ulceration was evaluated as described by other investigators,<sup>9-11</sup> scoring both the number and the size of the lesions as illustrated in Fig. 3. The results which are compiled in Table III were striking. The majority of the animals treated with 20 mg per kilogram of Thephorin were free of the typical numerous lesions found in all control animals. Only one perforation had occurred after 20 mg per kilogram Thephorin in contrast to seven in the controls. The lower doses of Thephorin had a proportionally lesser effect, 10 mg per kilogram Thephorin being approximately equivalent to 10 mg per kilogram of atropine. Although gastric juice was collected from the surviving animals

and analyzed for the amount of free hydrochloric acid the data are useless for comparison since the stomach contents of the surviving control animals had a relatively high pH caused by the buffering action of blood from the lesions. To gather information about possible differences in acidity and the amount of pepsin between control animals and rats pretreated with 20 mg per kilogram Thephorin, a five hour experiment was carried out. Since practically no ulceration had occurred within this period the true hydrogen ion concentration values of the gastric juice could not be ascertained. The average results for volume, pH, and pepsin concentration—the latter determined by the method of Kleiner<sup>22</sup>—are recorded in Table IV. The figures obtained from the animals pretreated with 20 mg per kilogram Thephorin are somewhat lower than those from the control animals, but hardly significantly.

#### DISCUSSION

Thephorin has a definite effect in reducing the gastric secretion induced in dogs by histamine. This particular antihistaminic action of Thephorin is less marked than its action against other important effects of histamine. In a series of experiments the volume of gastric juice secreted was reduced by 30 per cent which corresponds to the inactivation of 75 per cent of the administered histamine.

Contrary to reports in the literature<sup>14</sup> we succeeded in producing gastric ulcers in rats by repeated administration of histamine. The incidence of ulcer formation was markedly decreased after Thephorin in contrast to control animals and rats pretreated with atropine.

The fact that the rats had been used previously for a vitamin A assay may have been an important factor for the occurrence of ulcers. It has been reported<sup>23, 24</sup> that vitamin A deficiency per se leads to gastric ulcer formation in rats. The possibility whether a low vitamin A intake earlier in life is a predisposing factor for the production of ulcers by histamine in rats has to be considered. This problem is now under investigation and preliminary experiments seem to indicate that high doses of vitamin A have a prophylactic effect against histamine-induced ulcer formation.

Quite different were the results on ulcer formation in Shay rats. Under these experimental conditions both Thephorin and atropine were equally effective in protecting rats against ulcer formation. Considering the small difference in hydrogen-ion concentration and in the amount of pepsin between controls and treated animals, the antiulcer action of Thephorin cannot be explained by its inhibiting effect on the secretion of gastric juice. It has been shown<sup>14</sup> that vagotomy can prevent ulcer formation in Shay rats in the presence of a high acid concentration. The antiulcer effect of atropine is explained by its peripheral vagal blocking action, but this is unlikely to be the case with Thephorin since it was demonstrated that its anticholinergic effects are relatively weak as compared with atropine.<sup>17, 18</sup> The possibility has to be considered that a central mechanism is involved in the prophylactic action of Thephorin which is effective in the presence of a relatively high acid concentration. It is generally assumed that the degree of acidity, although a major factor in the genesis of peptic ulcer, is not the sole cause.<sup>25</sup> The evidence accumulated in these studies suggests that the action of Thephorin represents a chemical vagotomy.

It seems unlikely that histamine is the causative agent of the lesion occurring in Shay rats since atropine has a marked antiulcer effect under these experimental conditions but does not prevent histamine-induced ulcer formation.

#### SUMMARY

The antiulcer effect of Thephorin in Shay rats was striking. The evidence available suggests that the effect may be considered as chemical vagotomy.

Thephorin prevented to a marked degree gastric ulcer formation in rats produced by repeated histamine administration. Atropine was ineffective.

Thephorin reduced histamine-induced gastric secretion in dogs with Heidenhain pouches by about 30 per cent.

## THE EFFECTS OF INTRAVENOUSLY ADMINISTERED HISTAMINE ON THE PERIPHERAL CIRCULATION IN MAN

KHALIL G. WAKIM, M.D., PH.D.,\* GUSTAVUS A. PETERS, M.D.,†

JEAN C. TERRIER, M.D.,‡ AND BAIRD T. HORTON, M.D.†

ROCHESTER, MINN.

THE use of continuous intravenous administration of histamine as a therapeutic agent in certain diseases made us interested in a study of its effects on the peripheral circulation in the patients receiving the drug. Benson and Horton<sup>1</sup> studied the effects of continuous intravenous injection of histamine on the blood pressure and heart rate in patients with multiple sclerosis. They did not obtain a significant change in the systolic blood pressure, but the diastolic blood pressure showed an average fall of 17 mm. of mercury with a range of fall of 9 to 27 mm. of mercury below the control value. Within ten minutes after administration of the drug had been stopped, the pressures returned to within 3 mm. of mercury of their original levels. The heart rate increased an average of thirty beats per minute, with a range of increase from twenty-three to thirty-nine beats per minute. The heart rate also returned quickly to control levels after administration of histamine had been stopped.

In an excellent study of the systemic effects of histamine in man, Weiss and associates<sup>2</sup> reported that histamine is promptly converted into inactive substances in the human body. They found the minimal effective amount of histamine base in man to be about 0.003 mg. per minute. In observations of two hours' duration histamine up to toxic doses failed to produce any lowering of systolic arterial blood pressure, but the diastolic pressure showed only a tendency to fall and in many instances it also remained unaltered. They stated that the effect of histamine on the cutaneous blood vessels is not uniform. The most characteristic effect is dilatation of the venules, independent of the dilator effect on the arterioles. In some cases the evanescence and lack of elevation of the cutaneous temperature suggested a failure, even of toxic doses, to dilate the arterioles. Sometimes larger doses are needed to dilate the arterioles than those that dilate the venules. The intravenous infusion of 0.02 to 0.03 mg. of histamine base per minute increased the minute cardiac output about 20 per cent over the control value and was accompanied by a slight reduction in stroke volume. A slight but distinct increase in the mean velocity of blood flow was noted.

Harmer and Harris,<sup>3</sup> and also Carrier,<sup>4</sup> stated that histamine produced dilatation of the skin arterioles in man. Harmer and Harris noted an increase in heart rate of twenty beats per minute but were unable to detect plethysmographically any increase in blood flow to the limb as a whole in human subjects.

Received for publication Oct. 30, 1948.

‡Special Fellow in Physical Medicine, Mayo Foundation.

under the influence of histamine. Thermocouples, however, showed a rise in skin temperature which was interpreted as indicating that the blood is flowing more quickly through the skin vessels. When histamine was given intravenously they noted that the effects were complete in three to four minutes. One twentieth milligram of histamine hydrochloride increased cutaneous blood flow. Reddening of the skin and rise in skin temperature were definite. The systolic and diastolic blood pressure fell slightly and there was some increase in heart rate. Carrier reported that the application of histamine to the base of the fingernail in normal human beings in a dilution from 1 1,000 to 1 10,000 caused widening of the capillaries and acceleration of capillary blood flow.

In summarizing the evidence Best and McHenry<sup>1</sup> stated that small doses of histamine have little if any effect on the heart but somewhat larger doses increase the force and rate of the heartbeat in most species.

Anrep<sup>6</sup> reported that histamine dilated the coronaries in the human heart lung preparation.

In a study of the vasodilator action of histamine and its physiologic significance, Burn and Dile<sup>7</sup> explained the difference in reaction to histamine observed in various species of animals as being due to the variation of the level at which the constrictor effect of histamine on the central portion of the vascular tree changes to a dilator effect on the peripheral portion. In the dog the constrictor effect changes to a dilator effect at the level of the small visible arteries. In the cat the constrictor effect is present even at the level of the arterioles but mostly in the capillaries. In the rodents, the constrictor effect is pushed so far to the periphery that its change to a dilator effect escapes detection.

From his work on histamine shock Rich<sup>8</sup> concluded that histamine exerts a local dilator effect on capillaries and on the smallest arterioles and venules which border the capillary system. The circulatory failure in histamine shock is due to dilatation of the peripheral vascular bed.

From the work of Dile and associates<sup>7, 9, 11</sup> and Weiss and associates<sup>2</sup> it is suggested that there probably exists a shift in the locus of action of histamine as the evolutionary tree is ascended. Arterial constriction may be the predominant effect in rodents. In the cat there is a slight constriction of the arterioles, but the capillaries are dilated. In the dog and the monkey both arterioles and capillaries dilate. In man also the arterioles and the capillaries of the skin and of the brain dilate.

Since as the literature convincingly indicates the action of histamine varies in different species it is hazardous to interpret its action in man by observations obtained from animal experimentation. This makes it obvious that in order to obtain information on the action of histamine in man the observations should be made on man. This study deals with the effects of histamine on the peripheral circulation in human beings who were given histamine for therapeutic purposes and who volunteered for the investigation. The clinical observations and the laboratory data were obtained simultaneously on the

same subjects, in order to avoid species or individual differences, and under the same conditions, in order to avoid as many as possible of the factors that might introduce variations

#### METHODS

Human subjects who were receiving histamine intravenously by infusion over a period of about two hours for therapeutic purposes volunteered for this study. Before the observations were started, the patient was asked to lie quietly on a comfortable bed for about thirty minutes in a constant temperature room at 77° F with a humidity of about 40 per cent. Blood flow studies on all four extremities were made by means of the venous occlusion plethysmograph with a compensating spirometer recorder<sup>12</sup>. The arm plethysmographs included the hand, wrist, forearm, and part of the arm up to 2 inches (about 5 cm) above the olecranon process. The leg plethysmographs included the foot, ankle, and leg up to 1 inch (about 2.5 cm) below the tibial tuberosity.

The cutaneous temperatures were recorded galvanometrically by means of thermocouples applied to the forehead, to the skin over the right and left deltoid muscles, and over the right and left quadriceps femoris muscles. All five thermocouples were kept in position throughout each period of observation (more than two hours), and the temperatures were recorded as required at intervals.

The heart rate and systolic and diastolic blood pressure were recorded by the usual clinical procedures.

Histamine diphosphate was administered to each patient intravenously by continuous infusion in a concentration of 1:250,000 in physiologic saline solution at successive rates of 0.004, 0.008, 0.016, 0.020, and 0.024 mg of histamine diphosphate per minute respectively. The duration of infusion at each rate was twenty minutes. Control values for skin temperatures, heart rate, blood pressure, and blood flow were established before the infusion of histamine was started. All the observations were repeatedly taken at regular intervals thereafter for each of the periods of infusion at each of the infusion rates and for five to fifteen minutes after the infusion had been stopped.

#### RESULTS

Table I presents the percentage change in blood flow in the four extremities of subjects that were given histamine diphosphate intravenously by continuous infusion at the various rates specified. It can be stated generally that the magnitude of increase in blood flow of the upper extremities is greater than that of the lower extremities and that in both cases the increase is roughly proportional to the dose of histamine administered; namely, the larger the dose, the greater the increase in blood flow. In a few cases, especially when small doses of histamine were given, there was a transient reduction in blood flow in one or more extremities. Because Patients 8 and 21 could not tolerate higher dosage, the infusion of histamine was stopped at the dose of 0.016 mg per minute. Five minutes after the intravenous infusion of histamine had been stopped, the augmentation in blood flow was very much reduced. Evidently, as indicated from this work and from others,<sup>2, 13, 14</sup> considerable amounts of histamine are rapidly inactivated in the body.

The changes in the systolic blood pressure produced by the intravenous infusion of the amounts of histamine used in the study were insignificant, but the diastolic pressure showed a consistent drop of 10 to 15 mm of mercury. However, soon after the infusion of histamine had been stopped, the blood pressure returned to the control level.

TABLE I PERCENTAGE CHANGE OVER CONTROL BLOOD FLOW IN THE EXTREMITIES DUE TO INTRAVENOUS ADMINISTRATION OF HISTAMINE

Percentage change in blood flow

TABLE II AVERAGE CHANGE IN CUTANEOUS TEMPERATURE DURING INFUSION OF HISTAMINE (TEN CASES)

THERMOCOUPLE AREA	CUTANEOUS TEMPERATURE BEFORE HISTAMINE	AMOUNT OF HISTAMINE GIVEN (MG PER MIN)				
		0.004	0.008	0.016	0.020	0.024*
Forehead	34.1° C	0.2° C	0.2° C	0.3° C	0.2° C	0.2° C
Right shoulder	32.4	0	0.1	0.5	1.0	2.2
Left shoulder	32.8	0.1	0.4	1.1	1.3	1.8
Right thigh	31.3	0.4	0.6	1.4	1.8	3.1
Left thigh	31.7	0.5	0.6	1.2	2.1	3.6

\*Three cases only

In eight subjects the heart rate was taken during infusion of the drug at the various rates. The average increases in heart rate over the control value were six beats per minute for the infusion rate of 0.004 mg of histamine per minute, six beats for the rate of 0.008 mg per minute, nineteen beats for the rate of 0.016 mg per minute, and twenty-three beats for the rate of 0.020 mg per minute. Within ten minutes after the infusion of histamine had been stopped, the pulse rate practically returned to the control value.

Table II shows the average rises over the control temperatures produced during the intravenous infusion of histamine. It can be stated generally that, with the exception of the forehead, the greater the rate of infusion of histamine, the greater the rise in cutaneous temperature. Soon after the infusion of histamine had been stopped, the cutaneous temperature began to subside toward the control level.

As seen in Table II, the changes in skin temperature were greater over the lower extremities than over the shoulders and forehead. This is attributable to the relatively much greater perspiration over the forehead and shoulders than over the mid-region of the lower extremities. We believe that the cooling due to the accumulated fluid secreted by the sweat glands under the thermocouples accounts for the relatively lower temperature recorded from the skin over the forehead and shoulders.

## COMMENT

When it was repeatedly observed that the flushing and increase in blood flow were greater in the upper parts of the body and in the upper extremities than in the lower extremities, three possible explanations came to mind. The first two and more probable ones were as follows: (1) The upper parts of the body (face, neck, and arms) are usually more directly exposed to the environmental factors and consequently more intrinsic histamine and histamine-like substances are continuously liberated. This endogenous histamine supplemented the effect of infused histamine and gave findings of greater magnitude in the upper extremities than in the protected lower extremities. (2) The presence of a vasomotor gradient, vasoconstriction being least in the face, progressively increasing downward, and becoming highest in the toes, may account for the differences in degree of flushing and redness, which were greatest in the face and were progressively less till they were almost unnoticeable over the legs during the administration of histamine.

Fundamental differences in the vasomotor reactions of the hands and feet have been observed. Pickering and Hess<sup>1</sup> reported that in normal subjects the vasodilatation in response to warming of the body becomes evident in the fingers earlier than it does in the toes. They concluded that the delayed response of the toes as compared with the fingers, is attributable not to a difference in time but to a difference in intensity of the vasomotor relaxation in upper and lower extremities. As a result of warming of the body, loss of vasoconstrictor tone in the upper extremities is complete while in the lower extremities it is incomplete.

Horton and associates<sup>1</sup> noted prompt rise in the surface temperature of the fingers in patients given typhoid vaccine intravenously, whereas there was a distinct lag in the rise in surface temperature of the toes as compared with that of the fingers.

A distinct vasomotor gradient was demonstrated in normal subjects with reference to the face, hands and feet after administration of alcohol. The maximal degree of vasodilatation was in the face with decreasing degrees in the hands and feet. Regardless of the vasodilator agent used the rise in surface temperature appeared first in the face then in the fingers and later in the toes. The degree of vasoconstriction is greater in the toes than in the fingers. The upright posture in man may account for the greater degree of vasoconstriction in the lower extremities as compared with that of the upper. The difference in intensity of vasoconstriction in the toes and fingers may not be evident in terms of surface temperature but is easily demonstrated when vasodilator agents are administered.

A third possibility that because the arm veins were used for infusion the upper parts of the body received more histamine before it was exposed to the destructive enzymes of the blood and tissues was disproved and eliminated when we gave the infusion of histamine several times into the leg veins instead of the arms and still the flush and increase in blood flow were greater in the upper parts of the body and upper extremities than in the lower extremities.

#### SUMMARY

Intravenous administration of histamine diphosphate in a concentration of 1:250,000 in saline solution at successive rates of 0.004, 0.008, 0.016, 0.020 and 0.024 mg. per minute respectively produced cutaneous vasodilatation which appeared first over the face and neck of the patient and gradually extended downward over the upper extremities and thorax, reaching the lower extremities only toward the end of the period of observation when the higher rates of infusion were used. There was a definite increase in skin temperature and in heart rate and a slight decrease in diastolic blood pressure.

The blood flow in the four extremities gradually increased in proportion to the dosage used until at the highest rate of infusion of 0.024 mg. of histamine per minute the average increase in blood flow over the control values was 244 per cent in the left arm, 120 per cent in the right arm, 76 per cent in the left

leg, and 28 per cent in the right leg. However, five minutes after the infusion of histamine had been stopped, the increase of blood flow averaged only 46 per cent in each of the arms, 40 per cent in the left leg, and 14 per cent in the right leg. The changes in skin temperature, blood flow, heart rate, and blood pressure gradually subsided, and the values returned toward the control level shortly after the infusion of histamine had been stopped.

## PHOTOELECTRIC DETERMINATION OF ARTERIAL OXYGEN SATURATION IN MAN

DARL H WOOD M D PH D \* AND J E GERACI, M D †  
ROCHESTER, MINN

WITH THE TECHNICAL ASSISTANCE OF M NEHER AND L CRONIN

THE Matthes,<sup>1</sup> Millikan<sup>2</sup> and Goldie<sup>3</sup> oximeters have greatly facilitated the study of changes in arterial oxygen saturation in man. However, since these instruments must be preset to known arterial saturation values they cannot be conveniently used in patients who may have arterial hypoxia, nor can they be used for the actual determination of arterial oxygen saturation. Furthermore, extensive calibration studies with the Millikan compensated circuit oximeter carried out in this laboratory have yielded such variable results that it has been concluded that oximeter saturation readings are of only qualitative value in indicating changes in arterial oxygen saturation. Consequently studies have been carried out in an attempt to eliminate or minimize these shortcomings of the instrument.

A device will be described herein which can be used to measure the absolute value of, and follow continuously the changes of the arterial oxygen saturation from a pickup unit attached to the pinna of the human ear. This is accomplished by means of a photoelectric earpiece which allows simultaneous measurement of the transmission of red and near infrared light through either the normal heat flushed ear or the bloodless ear. Then by calculation, the light transmission of the blood alone in these spectral regions can be determined and in turn the percentage oxygen saturation of this blood content can be derived.

### OPERATION AND CONSTRUCTION OF THE INSTRUMENT

Although it was originally assumed that the Millikan oximeter responded to transmitted light in the region of the red and the green,<sup>2</sup> it has been pointed out<sup>4,5</sup> that whole blood films of approximately 1 mm depth transmit practically no light of a wave length shorter than 600 millimicrons.<sup>7</sup> The normal human ear has similar characteristics.<sup>8</sup> Therefore the operation of the oximeter is based on differences in transmission of light by oxygenated and reduced hemoglobin which occur in the red and near infrared rather than in the red and green portions of the spectrum as originally supposed.

The Millikan oximeter earpiece contains two barrier layer iron selenium photoelectric cells, each covered by a specific Wratten gelatin optical filter. Assuming a constant light source in the earpiece the amount of light transmitted

## PHOTOELECTRIC DETERMINATION OF ARTERIAL OXYGEN SATURATION IN MAN

EARL H. WOOD, M.D., PH.D.\* AND J. E. GERACI, M.D.†  
ROCHESTER, MINN.

WITH THE TECHNICAL ASSISTANCE OF M. NEHER AND L. CROWN

THE Matthes<sup>1</sup>, Millikan<sup>2</sup> and Coddet<sup>3</sup> oximeters have greatly facilitated the study of changes in arterial oxygen saturation in man. However, since these instruments must be preset to known arterial saturation values they cannot be conveniently used in patients who may have arterial hypoxia, nor can they be used for the actual determination of arterial oxygen saturation. Furthermore, extensive calibration studies with the Millikan compensated current oximeter carried out in this laboratory have yielded such variable results<sup>4</sup> that it has been concluded that oximeter saturation readings are of only qualitative value in indicating changes in arterial oxygen saturation. Consequently, studies have been carried out in an attempt to eliminate or minimize these shortcomings of the instrument.

A device will be described herein which can be used to measure the absolute value of and follow continuously the changes of the arterial oxygen saturation from a pickup unit attached to the pinna of the human ear. This is accomplished by means of a photoelectric earpiece which allows simultaneous measurement of the transmission of red and near infrared light through either the normal heat flushed ear or the bloodless ear. Then by calculation, the light transmission of the blood alone in these spectral regions can be determined and in turn the percentage oxygen saturation of this blood content can be derived.

### OPERATION AND CONSTRUCTION OF THE INSTRUMENT

Although it was originally assumed that the Millikan oximeter responded to transmitted light in the region of the red and the green,<sup>2</sup> it has been pointed out<sup>5,6</sup> that whole blood films of approximately 1 mm. depth transmit practically no light of a wave length shorter than 600 millimicrons.<sup>7</sup> The normal human ear has similar characteristics.<sup>8</sup> Therefore the operation of the oximeter is based on differences in transmission of light by oxygenated and reduced hemoglobin which occur in the red and near infrared rather than in the red and green portions of the spectrum as originally supposed.

The Millikan oximeter earpiece contains two barrier layer iron selenium photoelectric cells, each covered by a specific Wratten gelatin optical filter. Assuming a constant light source in the earpiece, the amount of light transmitted

Fig 1—Modified oximeter earpiece. A, inlet to pressure capsule B, pressure capsule C, rubber diaphragm of pressure capsule (capsule inflated to 10 mm. of mercury) D housing for photoelectric cells E leads to light bulb F adjustable carrier of light bulb and pressure capsule G, adjustable clamp to fix position of light bulb and pressure capsule H leads to photocells

through the pinna of the ear and the filters to the photoelectric cells is a function of the fixed characteristics of the respective filters, the amount of ear tissue, and the amount and state of oxygenation of the blood in the path of light

One of the photocells is covered by a green Wratten 61N filter, which transmits light in the spectral region from 480 to 600  $m\mu$  and in the region above 750 millimicrons. This cell, which has been called the "green cell," actually responds to light in the near infrared. This is due to the fact that the ear absorbs practically all light of a wave length shorter than 600  $m\mu$  and the response of the photocell falls practically to zero for light of a wave length greater than 850 millimicrons. Therefore this cell (the "infrared cell") is activated only by light of a wave length of approximately 800 millimicrons. Since oxygenated and reduced hemoglobin transmit light of this wave length to practically the same degree,<sup>6, 10</sup> the output of the infrared cell is a function of the amount of ear tissue and blood in the optical path and is independent of the degree of oxygenation of this blood.

The other photocell is covered by a red Wratten 29F filter, which transmits light of wave lengths greater than 600 millimicrons. The percentage transmission of red light (600 to 750  $m\mu$ ) is very different for oxygenated and for reduced hemoglobin<sup>11, 12</sup>. Hence the output of this cell (the "red cell") is a function of the amount of ear tissue and *both the amount and the degree of oxygenation* of the blood in the path of the light. If the ear tissue and amount of blood are constant, the output of the red cell is a function of the oxygen saturation of the blood interposed in the optical path of the earpiece.<sup>1, 12</sup>

In the Millikan oximeter the amount of ear tissue and blood in the optical path is compensated for by adjusting the instrument to indicate a known value of saturation (usually 98 or 100 per cent when the subject is breathing air or 100 per cent oxygen) while the earpiece is in place on the ear on which it is to be used. Variations in the amount of blood in the optical path are then compensated for automatically by balancing the output of the infrared cell against the output of the red cell.

The instrument to be described is based on the same spectral transmission characteristics of hemoglobin as is the Millikan oximeter. It differs, however, in the type of earpiece, infrared filter and electrical circuits used.

The earpiece (Fig. 1) differs from the earpiece of the Millikan oximeter in that the light source instead of being fixed in position is incorporated into an adjustable cylindrical housing designed so that it can be fixed securely in

Fig. 2.—Circuit diagram of modified oximeter. *I* inlet to pressure capsule. *G* glass disk. *C* rubber diaphragm. *G* galvanometer (50 cm scale, coil resistance 3,800 ohms, critical damping resistance 50,000 ohms, sensitivity 0.0006 microampere per millimeter deflection, period 4 seconds). *I* iron selenium photoelectric cell covered by a Wratten 84 infrared filter (dashed line). *R* iron chloran photoelectric cell covered by Wratten 9F red filter (dotted line). 50 K 50,000 ohm potentiometer control for infrared cell. 5 K 5,000 ohm potentiometer control for red cell.

the desired position relative to the ear. The end of the light housing which comes in contact with the ear contains an airtight chamber, the pressure capsule. The surface of the pressure capsule toward the light bulb is of glass, while the surface toward the ear is covered with a thin translucent rubber dam, thus absorption by the capsule of the light being transmitted from the light bulb to the ear is relatively small. A 1 cm length of No. 22 gauge hypodermic tubing serves as an inlet to the pressure capsule and is connected to a hand bulb and mercury manometer by means of a suitable length of vinyl tubing. When the earpiece is placed on the ear, the unit housing the light is adjusted so that the end (covered with rubber dam) fits snugly but not tightly against the front surface of the pinna. Thus when the pressure capsule is inflated to arterial

occlusive pressures (200 mm of mercury) the pinna is compressed between the rubber diaphragm and the flat, front surface of the photocell housing so that the blood is squeezed from the portion of the ear within the optical pathway of the earpiece. The photocells are covered with a mask containing a circular opening 12 mm in diameter, which is 8 mm less than the diameter of the surface of the pressure capsule. Masking of the photocells in this manner assures that all light reaching the cells is transmitted through a portion of the ear which can be efficiently pressurized by the capsule.

An infrared Wratten 87 gelatin filter is used to cover the infrared cell in place of the Wratten 61N filter used in the ordinary oxymeter earpiece. Falsely high values for the infrared transmission of the bloodless ear are obtained if the 61N filter is used, since it has been found that the "bloodless ear" transmits significant amounts of light in the green spectral region transmitted by the 61N filter.

The outputs of the red and the infrared cells are recorded separately by means of galvanometers<sup>f</sup> which have a sensitivity such that 0.0006 microampere produces a deflection of 1.0 millimeter. A schematic diagram of the circuit used is shown in Fig. 2.

#### PROCEDURE

The earpiece is placed on an optical filter† (E 100) and allowed to become warm. The infrared and red cell outputs are adjusted by regulating their respective variable resistors to produce equal galvanometer deflections (usually 50 to 70 mm depending on the anticipated optical density of the ear). Readings are then taken in succession on the E 100, E O, and E R test filters,‡ after which the earpiece is placed on the ear. Galvanometer readings are recorded at intervals of sixty seconds until a constant value is reached, indicating that the ear has become fully flushed. Usually this occurs within ten minutes. The pressure capsule is then inflated to 200 mm of mercury and readings are recorded at intervals of thirty seconds for five minutes. The pressure is then released and readings are continued for an additional period of five minutes or until the completion of some observational procedure. Readings are usually taken at intervals of ten seconds during withdrawal of arterial blood samples and at intervals of thirty seconds during the administration of low oxygen mixtures. If the observational procedure is of more than thirty minutes' duration, the "bloodless ear readings" (pressure capsule inflated to 200 mm of mercury) are redetermined at the end of the period of observation. Readings on the optical filters are repeated at the end of the procedure in order to be certain that the response of the device has remained stable throughout the period of observation.

\*Rubicon box galvanometers (catalogue No. 3415) with a coil resistance of 1500 ohms, a critical damping resistance of 40,000 ohms, and a period of 5 to 6 seconds were used. A single galvanometer can be used by incorporating a double pole double throw switch so that either the red or the infrared circuit can be connected individually to the single galvanometer. A galvanometer specially designed for this instrument is available (Rubicon Company) consisting of two galvanometer elements housed in a single cabinet with a single direct (visual) reading scale 20 cm in length.

†The E-100 filter is composed of the following materials in the order in which they are named:

- 1 One piece of glass 21 mm in thickness ground on the inner surface with No. 3F carborundum grit.
- 2 One layer of tracing paper (Albanene tracing paper 195L-12 Keuffel and Esser Company, Hoboken, N. J.)
- 3 One Wratten 29F filter
- 4 Three layers of tracing paper
- 5 One Wratten 29F filter
- 6 One layer of tracing paper
- 7 One plain glass slide measuring 11 mm in thickness.

‡The E-O, E-100, and E-R filters were constructed empirically to simulate the transmission characteristics for near infrared and red light of an average bloodless ear and an ear flushed with 90 and with 30 per cent saturated blood respectively. The composition of the E-R filter is identical to that of the E-100 filter except that one of the 29F filters is replaced by a Wratten 70 filter. The E-O filter consists of an 0.50 Wratten neutral density filter interposed between the same glass components as used for the E-100 and E-R filters.

## CALCULATIONS

The amount of light absorbed by the portion of the ear interposed between the constant light source and the photocells of the earpiece is an inverse function of the logarithm of the galvanometer deflection produced by the output of the photocells. Furthermore, the total light absorption by this portion of the ear is an additive effect of the light absorbed by the ear tissue proper and by the blood contained in this ear tissue. Consequently the amount of light absorption by the blood contained in this ear tissue is a function of the difference between the light absorption of the bloodless ear and the light absorption of the blood containing ear.

Therefore a value which is a function of the absorption of infrared light by the blood ( $IR_n$ ) can be obtained by the following equation

$$IR_n = \log II - \log IR_s = \log \frac{IR}{IR_s}$$

in which  $IR$  is the galvanometer deflection produced by the infrared cell when the ear is rendered bloodless by the pressure capsule and  $IR_s$  is the galvanometer deflection produced by the infrared cell when the ear is in the normal blood containing state.

Similarly a value ( $R_n$ ) which is a function of the absorption of red light by the blood interposed in the optical path of the earpiece can be obtained by the expression  $R_n = \log \frac{R}{R_s}$  in which  $R$  is the galvanometer deflection produced by the red cell when the ear is rendered bloodless and  $R_s$  is the galvanometer deflection obtained from the blood containing ear.

The absorption of light by blood in the near infrared is a function of the total amount of hemoglobin contained in the blood. Likewise absorption of red light by this blood is a function of the amount of oxyhemoglobin and total hemoglobin. Therefore, the ratio  $R_n/IR_n$  is a function of the oxygen saturation of the blood interposed in the optical path of the earpiece. Since this blood is rendered arterial by the increase in blood flow through the ear produced by the heat of the earpiece,<sup>3, 4</sup> the expression  $R_n/IR_n$  gives a value which is a function of the percentage saturation of arterial blood with oxygen.

The exact nature of the relationship between  $R_n/IR_n$  and arterial oxygen saturation may be determined experimentally and a calibration curve which will allow oxygen saturation to be determined from  $R_n/IR_n$  ratios may be constructed.

## METHODS

The calibration and range of error of the instrument have been studied in three ways:

1. The ratio  $R_s/IR_s$  has been calculated from the readings of the instrument obtained when recording from thirty five ears of twenty three normal subjects (age range, 5 through 68 years) while they were breathing room air or 100 per cent oxygen. The values of  $R_n/IR_n$  obtained for each ear have been plotted against the arterial oxygen saturation on the assumption that the arterial oxygen saturation of these subjects was 97.9† and 100 per

The mathematical expression of this relationship can be derived on the basis that Beer's law applies to the transmission characteristics of red and infrared light by hemoglobin in circulating whole blood assuming (1) that the response of the infrared cell is completely independent of the oxygen saturation of the transilluminated blood.

$$S = \frac{100 K}{K-1} (\log R/R_s - \log IR/IR_s) - \frac{100 I}{I-1}$$

or (2) that the response of the infrared cell is not completely independent of the degree of oxygen saturation of the transilluminated blood.

$S = 100 (K \log R/R_s - K \log IR/IR_s) - [(I-1) \log IR/IR_s - (K-1) \log R/R_s]$  in which  $S$  is the per cent oxygen saturation of the transilluminated blood,  $I$ ,  $K$ ,  $I-1$ ,  $K-1$  and  $K$  are constants, the absorption coefficients of total oxygenated and reduced hemoglobin for red and infrared light and  $R$ ,  $R_s$ ,  $IR$  and  $IR_s$  are defined in the text.

The equations were derived by Mr. R. J. Stow, Fellow in Biology, Los Mayo Foundation.

† Average value based on Van Slyke analyses of arterial blood sample obtained from twenty nine resting subjects breathing air (altitude 1040 feet). Extreme values .44 to .101 per cent.

cent when breathing air and oxygen respectively. The average values obtained have been used to establish the calibration curve of the instrument in the region from 95 to 100 per cent arterial oxygen saturation (Fig 3)

2 By the use of an indwelling arterial needle,<sup>13</sup> blood samples have been obtained from the radial artery of five normal white and five normal Negro subjects after periods of two and a half to ten minutes of breathing each of the following seven gas mixtures

Fig 3.—Empirical calibration curve of modified oximeter earpiece (No 1) for photoelectric determination of absolute values of arterial oxygen saturation in man. Based on 211 simultaneous photoelectric and Van Slyke determinations of arterial oxygen saturation

air, 100 per cent oxygen, and 16, 14, 12, 10, and 8 per cent oxygen in nitrogen. Instrumental readings were recorded throughout the period of withdrawal of each of sixty-two arterial blood samples. These readings were averaged and the average value of  $R_H/IR_H$  for each sampling period was calculated. The values obtained have been plotted against the arterial oxygen saturation as determined by Van Slyke analyses<sup>14</sup> of the simultaneously withdrawn arterial blood samples (Fig 3)

3 Similar methods have been used to obtain instrumental readings during withdrawal of 150 arterial blood samples from a series of forty-five patients suspected to have arterial hypoxemia. Arterial hypoxemia in these cases was a result either of congenital cardiac anomalies or of acquired respiratory abnormalities. Polycythemia was present in the majority. The average values of  $R_H/IR_H$  calculated from the instrumental readings obtained over the period of arterial sampling have been plotted against the arterial oxygen saturations determined by the Van Slyke analysis of the blood (Fig 3)

The oxygen saturation was calculated after correction of the oxygen content by subtracting the amount of oxygen estimated to be in physical solution (0.3 and 2.0 volumes per 100 c.c. for normal subjects breathing air and oxygen respectively).

Determinations were made on both ears of nine of the subjects making a total of twenty nine ears studied while subjects were breathing 100 per cent oxygen. Average age of subjects was 30 years (5 through 68 years) six of the subjects were Negroes.

Figures in parentheses are extreme values.

Determinations were made on both ears of twelve of these subjects.

Arterial samples obtained under various conditions including rest walking on a treadmill and breathing gas mixtures containing from 8 to 100 per cent oxygen. Average age of patients was 7 years (3 through 55 years).

## RESULTS

The plot of the calculated values of  $R_R/IR_R$  against the simultaneous estimations of arterial oxygen saturation by Van Slyke analysis (Fig 3) does not reveal significant differences in the data obtained from the three groups of subjects studied. Therefore, all of these data have been used as a basis for constructing a calibration curve for the instrument. The empirical calibration curve (Fig 3) was drawn as the closest visual fit to the 211 experimental points.

When this calibration line was utilized, the photoelectrically determined values of arterial oxygen saturation of twenty normal subjects when breathing 100 per cent oxygen ranged from 94.6 per cent to 100 per cent. These subjects ranged in age from 5 through 68 years. Six were Negroes (Table I). The average arterial oxygen saturation as determined by Van Slyke analyses<sup>14</sup> of thirty-five arterial samples obtained from twenty normal subjects while they were breathing 100 per cent oxygen was 99.1 per cent and the range of values was from 97.3 to 101.1 per cent.\*

The photoelectric determinations of arterial oxygen saturation of twenty-three subjects when breathing air ranged from 92.4 to 99.7 per cent (Table I). The average arterial oxygen saturation as determined by Van Slyke analyses<sup>13</sup> of forty-six arterial samples obtained from twenty-nine normal subjects while breathing air (altitude 1,040 feet) was 97.9 per cent. The range of values was from 94.1 to 101.0 per cent.

At values of arterial saturation between 15 and 100 per cent, the standard deviation of the differences between 211 simultaneous photoelectric and Van Slyke determinations of arterial oxygen saturation was 2.9 percentage saturation points. This implies a likelihood of 95 per cent that determinations of arterial oxygen saturation by this photoelectric method will be within 5.8 per cent saturation of that obtained by Van Slyke analysis of a simultaneously withdrawn arterial sample. The range of variation was not appreciably different for white and Negro subjects and for patients with variable degrees of polycythemia (Table I).†

## COMMENT

Photoelectric determination of the oxygen saturation of blood samples *in vivo* has been successfully carried out by several investigators.<sup>8, 11, 17, 23</sup> Photoelectric determination of *changes* in blood oxygen saturation also has been accomplished in unopened arteries and veins and in the intact pinna of the human ear.<sup>1-3, 12, 24</sup>

The present report represents to the authors' knowledge, the first description of the determination of absolute values of arterial oxygen saturation in the intact pinna of the human ear. Squire<sup>24</sup> in 1940 described a method for the

\*When 100 per cent oxygen was breathed for periods of ten minutes the quantity of oxygen<sup>25</sup> carried in physical solution was assumed to be 2.0 c.c. per 100 cubic centimeters. Therefore the oxygen contents obtained under these conditions were corrected for this factor by subtracting the constant figure 2.0. Much of the variability in the arterial oxygen saturations obtained when breathing oxygen probably results from variations in the quantity of physically dissolved oxygen and hence erroneous corrections for this factor.<sup>26</sup>

†It is of interest that the instrument predicted the arterial saturation satisfactorily (1) when used on a patient whose blood contained 0.75 Gm. of sulfhemoglobin per 100 c.c. (2) when used over a scrubbed and blistered area on an ear and (3) when used on the ear a fold of skin on the neck and a fold of skin on the thorax of a patient who had dermatolysis.

determination of the quantity of blood in the web of the hand and its degree of oxygenation. He did not however use the method to determine arterial oxygen saturation and did not present data as to the accuracy of the method for determining the degree of oxygen saturation of the blood contained in the web of the hand.

The accuracy of the method described herein appears adequate for intermittent or continuous clinical determination of arterial oxygen saturation and should obviate in many cases the necessity of arterial punctures for this purpose. Multiple determinations on individual subjects have indicated that when large errors do occur they tend to be systematic for that subject. This is substantiated by the fact that nine of the fifteen instances in which the difference between simultaneous photoelectric and Van Slyke determinations exceeded 5 per cent occurred in three subjects.

The accuracy of the instrument was limited in part by the accuracy of the galvanometer readings. The instrument must be set so that the galvanometer deflections obtained with the bloodless ear are on scale (that is 120 mm with the galvanometers used). When the instrument was adjusted in this manner the average red cell deflection was 60 mm when the subjects' blood was 100 per cent saturated and was 40 mm when the subjects' saturation was decreased to an average value of 62 per cent by breathing 8 per cent oxygen. Under these circumstances an error of 1 mm in reading the galvanometer deflection produced by the red cell may result in an error of approximately 3 per cent in the predicted value of arterial saturation.\*

The accuracy of the photoelectric estimations of arterial oxygen saturation was not disturbed by the subjects walking on a treadmill at 17 miles per hour<sup>5</sup> consequently the method would appear to be readily applicable to the study of arterial oxygen saturation during various cardiovascular respiratory function tests<sup>5, 6</sup> and during operative procedures.

Previous oximeters have not been calibrated to indicate arterial saturations of less than 50 per cent. The present instrument however operates satisfactorily at very low levels of arterial oxygen saturation. Seven simultaneous photoelectric and Van Slyke determinations of arterial oxygen saturation have been made in four patients at levels of arterial oxygen saturation ranging from 15 to 21 per cent (Fig. 3). It is of considerable physiologic interest that three of these patients were conscious and rational and able to walk on a treadmill at 17 miles per hour with levels of arterial oxygen saturation which in normal persons would produce loss of consciousness within a few seconds.

Since the instrument was found to perform satisfactorily on very deeply pigmented ears (Negroes) it is probable that the method can be applied to the determination of oxygen saturation of the blood contained in any human or animal tissue which will allow application of a pickup unit and an incorporated pressure capsule so that the interposed tissue can be successfully transilluminated and subjected to arterial occlusive pressures.

\*Appreciable errors in saturation produced by the error in reading the galvanometer can be eliminated by use of compensated shunt boxes to reduce the galvanometer sensitivity during recording of the bloodless ear readings or by use of Rubicon type L galvanometers (catalogue No. 3515 Rubicon Company, Philadelphia, Pa.) which deflect linearly over a scale of 100 millimeters.

It should be pointed out that all of the data reported herein were collected by the same oximeter operator, using the same earpiece, control box, galvanometers, and voltage on the earpiece light source. Every effort was made to keep all conditions which might possibly affect the operation of the oximeter as constant as possible. Therefore the degree of applicability of these data to other earpieces and less rigidly controlled conditions is not certain.

Fig 4—Empirical calibration curves of modified oximeter earpieces Nos 1, 2, and 3 based on 211, 105 and 155 simultaneous photoelectric and Van Slyke determinations respectively of arterial oxygen saturation. Plotting the oxygen saturation (ordinate) as an inverse log scale extending from 5 to 10 causes the calibration curves to approach straight lines at arterial saturations of less than 90 per cent.

Sufficient data have been collected to establish the empirical calibration curves of two other direct reading earpieces. These earpieces differed from the one used for the present study in details of design and in the use of a double thickness SSA infrared filter in place of the 87 filter. The data were collected by several different oximeter operators (technicians) under a variety of conditions. The empirical calibration curves of these earpieces were found to be significantly different from the curve of the earpiece used herein (Fig 4), and the results were somewhat more variable (Fig 5).

The following factors have been determined to be responsible at least in part for the increased variability: (1) The pressure capsule must be fitted sufficiently snugly against the front surface of the ear so that no shift in position of the ear relative to the photocells can occur when the pressure capsule is inflated. (2) Changes in the voltage across the light source may produce significant changes in the calibration curves of the earpiece. (3) The orientation and

Fig. 5—Empirical calibration curve of modified oximeter earpiece No 3 based on 15 simultaneous photo electric and Van Slyke determinations of arterial oxygen saturation. The differences between the gasometric and photoelectric values were less than plus minus 6.0 per cent saturation in 94 per cent of instances. Eight of the ten determinations which exceeded this range were obtained on two subjects. The open and solid symbols are based on determinations made with the earpiece equipped with a pressure capsule with an external diameter of 15 and 1 mm respectively.

the distance of the filament of the light source from the photocells may alter the results obtained. A new earpiece has been designed which considerably facilitates the control of these factors.

Other than the possible variability between different earpieces, the chief disadvantage of the modified oximeter is that a calculation on the basis of four galvanometer readings reference to logarithmic tables and references to the empirical calibration curve are required in order to obtain the actual value of the arterial saturation.

Use of a nomogram (Fig 6) relating infrared and red galvanometer readings directly to arterial saturation greatly expedites this procedure. If there are 100 divisions in the galvanometer scale (Fig 7) and if during the initial bloodless ear reading the output of the photocells is adjusted so as to indicate 100, the normal (nonpressurized) ear readings can be obtained directly in terms of per cent of the bloodless ear readings. Arterial saturation then can be obtained by direct reference to the nomogram without the necessity of intermediary calculations.

Fig. 6—Calibration nomogram derived from empirical calibration curve of modified oximeter earpiece No. 3. The nomogram can be used most conveniently if the red and infrared cell galvanometer scales are constructed so as to have 100 divisions for full scale deflection (Fig. 7). If the instrument is adjusted so that the galvanometer readings are 100 in the bloodless state ( $R$  and  $IR$ ) then the galvanometer readings for the blood-containing state ( $R_b$  and  $IR_b$ ) will read directly in terms of percentage of the  $R_0$  and  $IR$  readings. Consequently the saturation value can be read directly from the nomogram without recourse to calculation.

Fig. 7—Galvanometer scale for modified oximeter. When these types of scale are used the sensitivities of the red and infrared circuits should be adjusted so that full scale galvanometer readings (0 and 100) are obtained in the bloodless state ( $P_0$  and  $IR$ ). Then the bottom scale galvanometer readings for the blood-containing state ( $R_b$  and  $IR_b$ ) will be directly in terms of the log ratio ( $\log \frac{IR}{IR_b}$  or  $\frac{R}{R_b}$ ) and will be in terms of percentage of the bloodless reading ( $100 R_b/P$  or  $100 IR_b/IR$ ) for the top scale.

If such a nomogram is not available the calculations required can be reduced to a single operation (division) if the bloodless ear readings are adjusted to the full scale galvanometer deflection and the galvanometer scale is calibrated to indicate deflections as the logarithm of the quotient of the full scale galvanometer deflection divided by the deflection<sup>o</sup> (Fig 7). Then the relative

arterial saturation (log ratio) can be obtained by dividing the red galvanometer reading by the infrared reading, and in turn the absolute value of saturation can be derived by reference to the empirical calibration curve of the earpiece being used

Electronic means can be devised to modify this instrument so as to indicate the arterial saturation directly on a single galvanometer scale. One of the simplest methods would be to incorporate the red and infrared cells into a differential bucking circuit as suggested by Matthes<sup>1</sup>. A circuit of this type has been devised (Fig 9). It is somewhat similar to that used by Millikan<sup>3</sup>, Hemmingway and Trylor<sup>8</sup> and Hartman and associates<sup>9</sup>. Calculations based on calibration data reported herein indicate that if this circuit operated according to the theory of its design the variability of the single scale method of operation would be approximately 60 per cent greater than with the double galvanometer method which has been used. However, if the single scale circuit is to operate as designed, it is necessary that the output of the photocells be independent of the

variations in their external load resistance encountered under operating conditions. Actually this has been found not to be the case.<sup>30</sup>

### SUMMARY

An instrument is described for the photoelectric determination of absolute values of arterial oxygen saturation in the intact pinna of the human ear.

The instrument has been calibrated by determinations made on twenty-three normal subjects while breathing air and 100 per cent oxygen and by comparing the photoelectric values with values for the saturation of arterial blood with oxygen determined by Van Slyke analysis of 211 simultaneously withdrawn arterial blood samples.

In the range from 15 to 100 per cent saturation of arterial blood with oxygen the standard deviation of the difference between the photoelectric and Van Slyke determinations of arterial oxygen saturation was 2.9 percentage saturation points. Ninety-five per cent of the 275 photoelectric determinations were within plus-minus 5 per cent saturation of values based on direct gasometric analysis.

The accuracy of the procedure does not appear to be affected by age, race, sex, or blood hemoglobin content of the subjects on whom the instrument is used.

# ISOLATION OF HERPES SIMPLEX VIRUS ON THE CHORIOALLANTOIC MEMBRANE

LEWIS L. CORILL, M.D.,\* HARVEY BLANK, M.D.,† AND T. F. MCNAIR SCOTT, M.D.  
PHILADELPHIA, PA.

WITH THE TECHNICAL ASSISTANCE OF LILLIAN T. SCHERMEHRHORN

SINCE the work of Gruter<sup>1a</sup> (1913) and of Lowenstein<sup>1b</sup> (1919) the standard technique for the isolation of herpes simplex virus has consisted of inoculating the suspected material onto the scarified cornea of a rabbit. More recently, several workers<sup>2</sup> have shown that the virus grows well in the embryonated egg and that this medium may be used for primary isolation of the virus. However, no data appear to be available on the comparative efficiency of the two methods for this purpose. As the egg technique is simpler and cheaper than the standard technique, it seemed profitable to determine whether it were equally efficient. The results of parallel isolations, using the two techniques, are herewith presented, together with certain information concerning the carrying-out of the technique, the standardization of the antibiotics used, and the type of diluent that has been found useful in the routine handling of the virus.

## EXPERIMENTAL

*Comparison of Chorioallantoic Membrane (CAM) and Rabbit Cornea*—Using the standardized techniques to be described later in this paper, material from twenty-seven patients with vesicular lesions of the skin or lesions of the mucous membranes was inoculated simultaneously on eggs and on rabbit corneas. The results shown in Table I indicate no significant superiority of either method. Subsequent studies in this laboratory, using the embryonated egg as the sole means of isolating herpes simplex virus, have given gratifying results. Since that comparative study was made over a year ago, virus has been isolated by this method from thirty-four patients with various clinical manifestations of herpes simplex infection. In addition, it has been possible to get a quantitative count of the amount of virus in herpes vesicle fluid simply by measuring the fluid in a calibrated capillary tube before diluting it with buffer and antibiotic mixture. From the dilution and the number of plaques on the membrane, one can easily compute the virus content of vesicle fluid at various stages of its development.

## TECHNIQUES

In order to compare the chorioallantoic membrane and rabbit cornea as media for the isolation of herpes simplex, the specimen, such as saliva or skin washings, was divided into two parts, one being inoculated onto both corneas of a rabbit, and the other, after suitable preparation, into eggs.

From The Children's Hospital of Philadelphia (Department of Pediatrics) and the Department of Dermatology and Syphilology, University of Pennsylvania School of Medicine.

These studies were supported in part by grants from the Lederle Laboratories Division of American Cyanamid Company and the National Foundation for Infantile Paralysis.

Received for publication Nov. 13, 1948.

\*Senior Fellow in Virus Research, National Research Council.

TABLE I. ISOLATION OF HERPES SIMPLEX VIRUS ON THE RABBIT CORNEA VS CHORIOALLANTOIC MEMBRANE

	RABBIT CORNEAS	CAM
Number of specimens tested simultaneously	27	7
Number of virus isolations	17	16
Number negative	10	11

*Rabbit Cornea Inoculation*—Both corners of young four to six pound rabbits were scarified with a sharp scalpel under ether anesthesia and the material to be tested for virus was dropped into the conjunctival sac and rubbed on the corner with a cotton swab. If the rabbit developed keratoconjunctivitis one of the eyes was removed for histologic section and if the rabbit died part of the

Fig. 1.—Rabbit cornea epithelial cells infected with herpes simplex. Characteristic intranuclear homogeneous inclusion bodies are surrounded by dense margined chromatin. Hematoxylin and eosin ( $\times 900$ ).

brain was used for serial passage and part was fixed for histologic section. It is well to emphasize at this point that the corner must be taken at the stage of early congestion, erythema and photophobia in order to demonstrate the maximal number of inclusion bodies.

*Corneal Response and Identification*—In specimens free of virus the corner is fully healed within twenty-four hours whereas the corner infected with herpes simplex shows progressive corneal opacities together with successive injection, laceration and purulent exudate of the bulbar and palpebral conjunctiva. The identity of the virus in exudates shown to be free of bacteria was established by (1) demonstration of typical intranuclear inclusion bodies in the epithelium

of cornea or metitating membrane (Fig 1), or in the brain when encephalitis and death occurred, (2) subsequent intracerebral inoculation with a known virulent strain of herpes virus, to test for immunity in those animals which recovered

#### PREPARATION OF SPECIMENS FOR EGG INOCULATION

*Suitable Diluent*—It has been shown frequently that the herpes simplex virus is quite unstable when suspended in physiologic sodium chloride solution, but is more stable when nutrient broth or serum is used as a diluent

Both serum and broth have certain technical disadvantages as satisfactory diluents for clinical specimens. A search was made, therefore, for a simple solution suitable for receiving specimens and for storage of strains of virus. The quantitative survival of several egg-adapted strains of herpes simplex virus was tested after storage up to one week at room temperature in 10 per cent normal rabbit serum, Tyrode's solution, nutrient broth, physiologic saline solution, and phosphate buffered saline at pH 7.2 containing 0.5 per cent gelatin. Our results confirmed previous findings that physiologic saline solution caused marked loss of virus within one to four hours' exposure. In all the other solutions the virus was stable for four hours or more, but deteriorated slowly thereafter. Storage at 4° C or at -20° C prolonged the viability of virus stored in all solutions except physiologic saline. Because of its ease of preparation and lack of antigenicity, the buffered saline-gelatin solution was adopted as the standard diluting fluid in our work<sup>2d</sup>. Nutrient broth also occasionally was employed.

*The Use of Antibiotics*—Clinical specimens that are normally free of bacteria (i.e., spinal fluid, blood) can be inoculated onto the egg membranes directly, other specimens normally contaminated with bacteria, such as saliva or vesicle fluid, usually kill the embryos from bacterial infection unless specially treated. It has been demonstrated<sup>3</sup> that sputum can be rendered safe for inoculation into eggs by treatment with penicillin and streptomycin. In relation to the isolation of herpes virus on the chorioallantoic membrane, the amount of antibiotic to be used is limited on the upper side by its toxicity both for the virus and for the chorioallantoic membrane, but must be sufficient to kill the bacteria usually encountered.

Contaminated specimens were collected on a sterile swab or capillary pipette and emulsified in 0.9 ml of buffered saline-gelatin solution or nutrient broth. To this tube was added 0.1 ml of a stock solution of penicillin and streptomycin. This mixture was allowed to stand ten to thirty minutes at room temperature before inoculation into the egg membranes.

*Toxicity of Antibiotics for the Chorioallantoic Membrane*—It was found that penicillin caused no appreciable changes in the chorioallantoic membrane when used in concentrations up to 10,000 units per milliliter, whereas streptomycin caused nonspecific opacities, marked thickening and edema, if applied in a concentration of 1,000 µg per milliliter or greater.

*Toxicity of Antibiotics for Herpes Virus*—Various concentrations of the two antibiotics mixed with a chorioallantoic membrane suspension of herpes simplex were tested for quantitative survival of the virus at intervals up to

twenty four hours after mixing. Ten thousand units per milliliter of penicillin and 250 µg per milliliter of streptomycin did not reduce the virus plaque count.

**Toxicity of Antibiotic Mixture on Chorioallantoic Membrane and Herpes Virus**—On the basis of the toxicity studies just described, a mixture of antibiotics was selected which gave a final concentration after being added to the virus containing specimen, of 500 units of penicillin and 100 µg of streptomycin. Many tests with this mixture showed that it was nontoxic for the chorioallantoic membrane, and that it did not appreciably diminish the amount of viable virus when tested against a laboratory strain of egg adapted HF virus.

**Effect of Antibiotic Mixture on Bacterial and Yeast Contaminants**—Most samples of sputum were rendered bacteriologically sterile by exposure to this antibiotic mixture for ten to thirty minutes. The antibiotic mixture was found to be still effective against bacterial contaminants after storage in a vaccine bottle at 4° C for up to two months. In the few failures observed the eggs were shown to be contaminated by yeasts or molds.

TABLE II ADDITIVE EFFECT OF MIXED ANTIBIOTICS FOR A BACTERIUM AND A YEAST FREQUENTLY FOUND IN THE MOUTH

ANTIBIOTIC	YEAST EFFECTIVE CONCENTRATION AGAINST	
	STREPTOCOCCUS*	C. ALBICANS†
Penicillin	0.026 u/ml	>500 u/ml
Streptomycin	100 u/ml	>100 u/ml
Crystal violet‡	1:200,000	1:100,000
Streptomycin	10 u/ml	—
+ Crystal violet	1:500,000	—
Penicillin	0.003 u/ml	25 u/ml
+ Streptomycin	0.0006 u/ml	5 u/ml
+ Crystal violet	1:750,000,000	1:1,000,000

In vitro tests by the Rammelkamp method for penicillin assay.

†In vitro tests with various amounts of antibiotic or mixtures added to 0.5 per cent glucose broth containing a standard inoculum of *C. albicans*. Subcultures made to glucose broth to determine the fungicidal concentration.

‡Coleman and Bell certified.

Since crystal violet is a well known fungicide, dilutions of crystal violet were tested for toxicity to the chorioallantoic membrane to the virus of herpes simplex, and to *Candida albicans* in order to see if it could be used to control the fungi occasionally encountered in sputum<sup>4</sup>. On the basis of these studies, crystal violet was added to the antibiotic mixture to make a final concentration in the clinical specimen of 1 to 50,000. Although the addition of crystal violet caused a precipitate to form (the crystal violet base apparently precipitates with the penicillin anion), the bactericidal properties of the mixture were enhanced rather than reduced as shown in Table II. This mixture sterilized sputum which was naturally or artificially contaminated with *C. albicans* and permitted the isolation of herpes simplex when present. In spite of its efficacy, crystal violet has not been used routinely because in our experience, contaminating fungi were seldom encountered.

**Inoculation of Eggs**—Two to four eggs prepared by the "false air sac technique"<sup>2a</sup> each were inoculated through the hole over the false air sac with 0.05

Fig 2—Chorioallantoic membrane of chick embryos forty hours after infection with herpes simplex. Each plaque is produced by one infectious unit ( $\times 30$ )

Fig 3—Section of chorioallantoic membrane infected with herpes simplex. A single plaque is present consisting of a proliferation of epithelial cells. Hematoxylin and eosin ( $\times 80$ )

Fig 4—High power section of Fig. 3. Marked proliferation of epithelial cell many of whose nuclei show margined chromatin and contain a characteristic homogeneous ground glass inclusion body. Hematoxylin and eosin ( $\times 600$ )

ml of the specimen to be tested. The hole was protected from dust by a piece of Scotch tape folded in such a way that the hole in the shell was not tightly sealed. If the hole is sealed completely the true air sac refills and the false air sac is gradually obliterated.

After inoculation the eggs were kept on their sides and incubated for forty eight to seventy two hours at 35 to 36° C. The identity of any virus isolated was established by (a) the gross appearance of the plaques on the chorioallantois (Fig 2), (b) by serial passage on the chorioallantoic membrane (c) by demonstration of the typical intranuclear inclusion bodies in histologic sections of the infected chorioallantoic membrane (Figs 3 and 4) (d) by neutralization tests with the newly isolated virus and hyperimmune rabbit serum.<sup>6</sup>

#### APPEARANCE OF INFECTED MEMBRANES

*Gross Characteristics*—The appearance of herpes simplex on the chorioallantoic membrane is well illustrated in Fig 2. Clear cut infection of the membrane with herpes virus produces small white plaques\* on primary isolation, these plaques may be 0.1 to 1.0 mm in diameter, but after several serial passages they average 0.5 to 1.0 millimeter. They are usually round or oval but may be elongated or tailed, they are dense in the center, with only a slight halo of mesodermal reaction. If the plaque is wiped off, which is easily accomplished, the mesodermal reaction can be seen as a faint shadow. If the infected membranes are incubated more than forty eight hours small satellite plaques may appear and they eventually interfere with an accurate enumeration of the original

\*For etymological reasons we prefer the term plaque to that of pock since the lesion consists of superficial proliferation of epithelial cells which appear to be applied to the surface (a plaque) rather than consisting of a pustule (a pock).

plaques In many successful isolations, there was gross evidence of virus on the first passage However, some virus strains grew poorly at first, and nonspecific opacities on the chorioallantoic membrane could be confusing, so that at least three serial passages were made before discarding a specimen as negative

*Microscopic Characteristics*—As soon as typical plaques were evident, a piece of the membrane was fixed for histologic examination Examination of the tissue under low power showed the plaque to be composed of proliferated ectodermal cells, with a minimum of inflammatory reaction in the mesodermal and endodermal cell (Fig 3) layers Many of the ectodermal cells in the plaque contained homogeneous intranuclear inclusion bodies (Fig 4) similar to those seen in the infected rabbit cornea or brain (Fig 1)

Hematoxylin and eosin staining of Zenker's acetic acid fixed tissue has been satisfactory for both animal and egg tissues

#### SUMMARY AND CONCLUSIONS

1 For the isolation and identification of herpes simplex virus, the chorioallantoic membrane of the embryonated egg is as reliable as the rabbit cornea

2 A suitable nonalleergic diluent for preserving the virus is 0.5 per cent gelatin in physiologic saline phosphate buffered to pH 7.2

3 Contaminated materials must be treated with an antibiotic mixture before inoculation A final concentration of penicillin 500 units per milliliter and streptomycin 100  $\mu$ g per milliliter is nontoxic to the herpes simplex virus and to the egg, but is bactericidal for saliva or skin washings For specimens containing yeasts not inhibited by penicillin and streptomycin, the addition of crystal violet in a final concentration of 1 to 50,000 is effective

4 The gross and microscopic appearances of herpes infected chorioallantoic membranes are described

## THE THERAPEUTIC EFFECT OF TRYPTOPHANE IN HUMAN PELLAGRA

RICHARD W. VILTNER, M.D. JOHN F. MUELLER, M.D.  
AND WILLIAM B. BEAN, M.D.  
CINCINNATI, OHIO

A METABOLIC relationship between tryptophane and niacin has been demonstrated in laboratory animals and in man. Kiehl, Tepley, Sarna and Elvehjem<sup>1</sup> showed that niacin deficiency induced in rats by a corn diet could be corrected by tryptophane as readily as by niacin. A similar metabolic relationship has been demonstrated in the pig<sup>2</sup> and the horse<sup>3</sup> and the cotton rat.<sup>4</sup> More recently Suttell and Goldsmith<sup>5</sup> and independently Perlzweig, Rosen, Levitas and Robinson<sup>6</sup> have shown that human adults and infants given 1 to 5 Gm. of tryptophane daily excrete a much larger amount of N<sup>1</sup> methyl nicotinamide in the urine than is found under basal conditions.

These experiments were suggested by the observation that diets which depend largely on corn and corn products for protein are more highly pellagragenic than diets equally low in niacin but which contain diversified proteins. The mechanism for such an effect was obscure until Kiehl, Tepley, Sarna and Elvehjem<sup>1</sup> showed that rats, a species not affected adversely by a diet deficient only in niacin, developed signs of niacin deficiency when fed a corn diet. Tryptophane restored these animals to health and it was suggested that a deficiency of tryptophane in the corn diet was the controlling factor. At first it seemed likely that tryptophane exerted its protective effect through the synthesis of niacin by enteric microorganisms.<sup>1</sup> More recent evidence however indicates that tryptophane may be a direct precursor of niacin, that the conversion occurs after absorption<sup>7-9</sup> and is influenced by pyridoxine.<sup>9, 10, 11, 12</sup>

The final proof of the effectiveness of this conversion in man depends upon the demonstration that tryptophane will relieve the acute manifestations of clinical pellagra. We wish to report such observations on one patient with acute pellagrous glossitis, dermatitis, vaginitis and diarrhea and another with chronic pellagrous dermatitis.

Each patient was fed a diet devoid of vitamin C and low in vitamins of the B complex. It had the following composition: calories 3127, protein 41.7 Gm., fat 27 Gm., thiamine 0.42 mg., niacin 4.2 mg., riboflavin 0.60 mg., vitamin C 0 mg., tryptophane 0.07 gram. Tryptophane was administered orally in 2 Gm. doses three times daily and twenty-four hour urine specimens were collected whenever possible and analyzed for N<sup>1</sup> methyl nicotinamide.<sup>13</sup> Normal values in our laboratory for N<sup>1</sup> methyl nicotinamide in the urine range from 2.5 to 5.5 mg. per twenty-four hours. Clinical observations were made daily by at least two observers.

From the Department of Internal Medicine, College of Medicine, University of Cincinnati.  
This study was aided by a grant from Merck & Co., Inc., Rahway, N. J. and the Robert Gould Research Foundation, Inc.

Received for publication Nov. 26, 1948.

## CASE REPORTS

CASE 1—M O, a 30 year old, unemployed, colored woman, was admitted to the Cincinnati General Hospital on July 15, 1948, complaining of painful feet, paresthesias, burning, numbness and swelling of the legs of two months' duration. Diarrhea consisting of four to eight brown liquid stools per day had been present for one month. She also had noted an eruption over the forearms and legs of unknown duration. She had lost 15 pounds of weight.

The patient stated that she ate two meals per day consisting of fatty pork three times a week, six eggs per week, one pint of milk per day, and some vegetables. She was addicted to alcohol. The dietary history could not be verified.

Physical examination revealed a chronically ill, malnourished Negress, moderately well oriented but with poor memory and below normal intelligence. Blood pressure, 140/90, temperature, 99° F, pulse, 90, respirations, 24. There were perfectly symmetrical pellagrous skin lesions on the wrists, dorsal forearms, ankles, legs, and knees. These were deeply pigmented, hyperkeratotic, and sharply demarcated from the surrounding normal skin. Over the bridge of the nose were numerous small hyperkeratotic hair follicles. The tongue was pale with the exception of the tip and edges where it was smooth, swollen, and spotted with clusters of very red, congested papillae, producing fiery red areas on a pale background. There were also spotty areas of stomatitis with one eroded area on the buccal mucous membrane. The eyes, neck, heart, and lungs were normal. The abdomen was normal except for scars from a bullet wound and a laparotomy. The vaginal examination revealed inflamed mucous membrane. There was moderate edema of the ankles. The neurological examination revealed normal reflexes and motor power, but there was marked hyperesthesia of the right foot and moderate hyperesthesia of the left foot from the ankles down, with afterglow in both feet.

**Laboratory Data** On admission, the erythrocytes numbered 3,400 million per cubic millimeter, the hemoglobin, 9.8 Gm per 100 cc, the hematocrit, 32 per cent, the reticulocytes, 3.8 per cent, the platelets, 289,000 per cubic millimeter, mean corpuscular volume, 94 cubic microns, mean corpuscular hemoglobin, 29 micromicrograms, mean corpuscular hemoglobin concentration, 31 per cent, and the white blood cells, 6,200 per cmm with a normal differential count. The bone marrow showed mild hypoplasia of all elements with a slight increase in plasma cells. The blood urea nitrogen was 3.7 mg per 100 cc, the prothrombin concentration, 65 per cent, the Kahn test, negative, thymol turbidity, 2 units, thymol flocculation, +, and cephalin flocculation, +++ in twenty four and forty eight hours. Serum

TABLE I. A TABULAR SUMMARY OF THE RESPONSE TO TREATMENT IN CASE 1, A PERSON WITH ACUTE PELLAGRA, PARTICULARLY THE EFFECT OF TRYPTOPHANE ON THE GLOSSITIS, VAGINITIS, DIARRHEA AND TWENTY FOUR HOUR EXCRETIONS OF N<sup>1</sup> METHYLNICOTINAMIDE IN THE URINE

Severity of diarrhea	++	++	++	++	++	++	++→0	0	0	0	
Urinary excretion of N <sup>1</sup> methyl nicotinamide (mg per 24 hr)			0.063			0.720		2.520		4.216	5.040

\*Fifty milligrams of thiamine were administered on this day and 25 mg on each day thereafter.

bilirubin was 0.15 mg. per 100 cc prompt 0.5 mg. per 100 cc total. The liver biopsy showed severe fatty vacuolization. The urine was negative and the stool a liquid brown color without blood, pus cells, ova or parasites. The electrocardiogram was normal. The total protein was 7.56 Gm per 100 cc with albumin 3.3 Gm per 100 cc and globulin 4.2 Gm per 100 cc. These tests were repeated in one week and the total protein was 6.2 Gm per 100 cc, albumin 2.65 Gm per 100 cc and globulin 3.55 Gm per 100 cubic centimeters. The serum vitamin C was 0 mg per 100 cc serum vitamin A was 40  $\mu$  per 100 cc carotene, 28  $\mu$  per 100 cubic centimeters. Thiamine excretion in the urine in twenty-four hours was 5.5  $\mu$ g and after a test dose of 5 mg by mouth the patient excreted less than 1 per cent of the test dose in four hours. Riboflavin urinary excretion in twenty-four hours was 434.5  $\mu$ g and in four hours after 5 mg of riboflavin by mouth 294 milligrams. For urinary N-methylmethionamide see Table I. X-rays of chest and abdomen were negative.

The patient was placed at bed rest and given a diet low in vitamin B complex and free of vitamin C. Because of the severe diarrhea twenty-four hour urine specimens could not be obtained prior to treatment.

On the second hospital day the tongue was redder and had a small serpiginous ulcer on the right lateral margin. That afternoon the patient was given 50 mg. of Demerol in preparation for a liver biopsy. That night he began to confabulate and had hallucinations. This psychotic behavior was thought to be due to B complex deficiency encephalopathy exaggerated by Demerol. On the morning of the third day tryptophane 2 Gm three times daily was started and a twenty-four hour urine specimen was obtained. On the next day the ulcer on the tongue began to heal although red papillae were still evident. The patient was still confused and paranoid and had hallucinations. By the fifth hospital day the tongue was much improved, the ulcer had healed but a few red papillae remained which disappeared by the next day. The psychotic behavior and the encephalopathy continued, however, and since severe vitamin B complex deficiency particularly of thiamine was thought to be the cause the patient was given 50 mg. thiamine and 10 mg. riboflavin on the seventh hospital day over an eighteen hour period. She was also given 2,000 cc of 5 per cent glucose in water intravenously. There was a rapid response. By that evening the psychotic manifestation had vanished. At this time the acute aspects of the skin lesions were regressing rapidly, the tongue was healed, the diarrhea controlled and the encephalopathy had cleared. Since tryptophane was available in only a limited quantity it was discontinued and a B complex material which contained 100 mg. of niacinamide per cubic centimeter was started. The patient received  $\frac{3}{4}$  cc at this time and on each day thereafter. The peripheral neuritis responded slowly but had cleared almost completely after two more weeks of treatment. The patient was discharged after twenty-six days in the hospital.

**CASE 2**—H. J., a 6-year-old colored common laborer was admitted to Cincinnati General Hospital on Sept. 23, 1948, from the city workhouse for study. He had no complaints except for skin lesions of four weeks' duration which he attributed to burns contracted while living drunk in the sun. He had noticed some numbness and tingling of the feet and mild diarrhea for an undetermined period of time.

His appetite was good. His diet consisted of ham skins, ham fat, potatoes, onions, celery, and cabbage all combined to make stew which he ate one to two times a day. He admitted heavy alcohol intake of at least one quart of Dril (denatured alcohol) per day. By mistake he had been given one vitamin capsule containing 30 mg. of niacin while in the workhouse hospital one day before admission.

In 1949 he had been in Cincinnati General Hospital with a diagnosis of pellagra, dermatitis and glossitis, polyneuritis and chronic alcoholism. On that admission the skin and mouth lesions cleared after treatment with niacin.

The physical examination revealed a well-developed, poorly nourished Negro man who did not appear ill. There were perfectly symmetrical pellagrous lesions involving the extensor surface of the forearms which were deeply pigmented, hyperkeratotic, scaling, and sharply demarcated from the surrounding normal skin. There were similar lesions

TABLE II THE EFFECT OF TRYPTOPHANE ON THE EXCRETION OF N<sup>1</sup> METHYLNICOTINAMIDE IN THE URINE OF CASE 2, A PERSON WITH CHRONIC PELLAGROUS DERMATITIS, THIS PATIENT RECEIVED 30 MG OF NIAIN INADVERTENTLY BEFORE THIS STUDY WAS BEGUN

DATE	9/23/ 48	9/24/ 48	9/25/ 48	9/26/ 48	9/27/ 48	9/28/ 48	9/29/ 48	9/30/ 48	10/1/ 48	10/2/ 48	10/3/ 48	10/4/ 48	10/5/ 48	10/6/ 48

N <sup>1</sup> methyl nicotinamide urinary excretion (mg / 24 hr)		464	1 11	1 33	1 84	2 94	3 936	7 665				1 785		

involving the collar area of the neck, the ear lobes, and to a lesser extent the groin and feet. The tongue showed only papillary atrophy along the margins. There was severe hyperesthesia and decreased vibration perception in the feet, and the ankle jerks were absent.

**Laboratory Data** The erythrocytes numbered 251 million per cubic millimeter, the hemoglobin, 9.06 Gm per 100 cc, and the white blood cells, 7250 per cubic millimeter with a normal differential count. The urine was normal. The serum protein was 6.85 Gm per 100 cc, urinary thiamine was 17.4 µg in twenty-four hours, and after a test dose (0.5 mg intramuscularly) 4.4 per cent was excreted in four hours. Urinary riboflavin was 1.16 mg in twenty-four hours. See Table II for N<sup>1</sup> methyl nicotinamide excretion.

The patient was placed on a diet low in vitamin B complex and free of vitamin C, and twenty-four hour urine specimens were collected. After three days he was given tryptophane, 2 Gm thrice daily until a total of 20 Gm was given. By the end of the first week the skin lesions had begun to clear and disappeared gradually during the next two weeks. The patient was discharged after twenty-one days in the hospital.

#### DISCUSSION

In the first case tryptophane orally in total daily doses of 6 Gm induced a remission in the acute pellagrous glossitis, stomatitis, vaginitis, and diarrhea. Concomitantly there was an increase in N<sup>1</sup>-methyl nicotinamide in the urine from extremely low to almost normal levels. Subsequently 50 mg nicotinamide daily induced a rapid and great increase in the amount of N<sup>1</sup>-methyl nicotinamide in the urine suggesting that tryptophane may have replenished the body stores of nicotinamide. In this patient the encephalopathy did not clear completely until thiamine was given, which suggests that it was due at least in part to thiamine deficiency.

The second case is included to show that tryptophane increased the amount of N<sup>1</sup>-methyl nicotinamide in the urine of a pellagrum rapidly to high levels just as it will in normal persons on diets restricted in niacin.<sup>4</sup> This subject was not ill when he was admitted to the hospital and it is probable that tissue niacin had been restored by the workhouse diet and the one dose of 30 mg niacin before he was hospitalized. The skin lesions in this patient, though typically pellagrous, were too chronic and indolent to allow critical judgment on the therapeutic effect of tryptophane.

# SUMMARY AND CONCLUSIONS

Tryptophane in 6 Gm oral doses induced a remission in typical acute pellagrous lesions

It caused an increased excretion of N<sup>1</sup> methylnicotinamide in the urine of pellagrins at a slower rate but in the same manner as in normal persons

These observations suggest that tryptophane and niacin are closely related in their role in human as well as in animal nutrition

We wish to acknowledge the technical assistance of Mrs Betty Fichter in performing the N<sup>1</sup> methylnicotinamide determinations and to thank Dr A Gibson of Merck & Co Inc, for a generous supply of tryptophane

involving the collar area of the neck, the ear lobes, and to a lesser extent the groin and feet. The tongue showed only papillary atrophy along the margins. There was severe hyperesthesia and decreased vibration perception in the feet, and the ankle jerks were absent.

*Laboratory Data* The erythrocytes numbered 2.51 million per cubic millimeter, the hemoglobin, 9.06 Gm per 100 cc, and the white blood cells, 7,250 per cubic millimeter with a normal differential count. The urine was normal. The serum protein was 6.85 Gm per 100 cc, urinary thiamine was 17.4 µg in twenty-four hours, and after a test dose (0.5 mg intramuscularly) 4.4 per cent was excreted in four hours. Urinary riboflavin was 1.16 mg in twenty-four hours. See Table II for N<sup>1</sup> methyl nicotinamide excretion.

The patient was placed on a diet low in vitamin B complex and free of vitamin C, and twenty-four hour urine specimens were collected. After three days he was given tryptophane, 2 Gm thrice daily until a total of 20 Gm was given. By the end of the first week the skin lesions had begun to clear and disappeared gradually during the next two weeks. The patient was discharged after twenty-one days in the hospital.

#### DISCUSSION

In the first case tryptophane orally in total daily doses of 6 Gm induced a remission in the acute pellagrous glossitis, stomatitis, vaginitis, and diarrhea. Concomitantly there was an increase in N<sup>1</sup>-methyl nicotinamide in the urine from extremely low to almost normal levels. Subsequently 50 mg nicotinamide daily induced a rapid and great increase in the amount of N<sup>1</sup>-methyl nicotinamide in the urine suggesting that tryptophane may have replenished the body stores of nicotinamide. In this patient the encephalopathy did not clear completely until thiamine was given, which suggests that it was due at least in part to thiamine deficiency.

The second case is included to show that tryptophane increased the amount of N<sup>1</sup>-methyl nicotinamide in the urine of a pellagrin rapidly to high levels just as it will in normal persons on diets restricted in niacin.<sup>4</sup> This subject was not ill when he was admitted to the hospital and it is probable that tissue niacin had been restored by the workhouse diet and the one dose of 30 mg niacin before he was hospitalized. The skin lesions in this patient, though typically pellagrous, were too chronic and indolent to allow critical judgment on the therapeutic effect of tryptophane.

## METHODS AND MATERIALS

The radioiron had an activity of 135 mc of Fe 59 and 31 mc of Fe 55 per gram at the beginning of the experiments. It was given orally or by stomach tube in the form of ferrous ammonium sulfate with milk or water as the vehicle. Samples of tissues and excreta were a bed and the iron was electroplated by the method of Vosburgh, Flexner and Cowie. Radioactivity was measured with a thin mica end window Geiger counter. Tissues for histochemical study were fixed in Carnoy's fluid and formalin or alcohol formalin and were stained for iron by Dry's modification of Perl's method<sup>3</sup> or by Gomori's method<sup>4</sup>. Radioautographs were prepared in duplicate. One paraffin section subsequently stained by Dry's method was used for a routine contact radioautograph with an eco non creen x ray film. A second section stained for iron was coated with collodion and a liquid photographic emulsion was poured on the slides and allowed to set and dry. After proper exposure the preparation was developed, fixed, dried, mounted in xylol Clarite and covered with a cover slip.

Animals used were guinea pig, albino rats and one dog. Guinea pigs of 240 to 450 grams were maintained for at least two weeks on a stock pellet diet containing .52 mg of iron per 100 grams. All food and water were withheld for twenty four hours before giving 20 mg of radioiron by mouth.

A number of guinea pigs made anemic one week prior to the experiment by one bleed mg of 5 to 10 cc from the heart also were given radioiron. Control animals both normal and anemic were treated identically except that no radioiron was administered to them. Animals were killed thirty minute to twenty two hours after administration of the test dose of iron. Controls were killed at identical intervals during the same period. The net absorption of the single dose of tagged iron was calculated by subtracting from the total dose that iron recovered in the excreta and gut content. Portions of mesenteric and cervical nodes, spleen and liver and samples of blood were washed and the content of radioiron was determined as micrograms per gram of tissue or blood.

Weanling rats of 40 to 60 grams were kept on purified diets containing 61 per cent sucrose, 25 per cent casein, 10 per cent Crisco and 4 per cent of Hubbel's salt mixture from which the iron was omitted. To each kilogram of diet were added 20 milligrams niacin, 40 milligrams calcium pantothenate, 0.01 milligram biotin, 20 milligrams riboflavin, 10 milligrams thiamine hydrochloride, 10 milligrams of pyridoxine, 1 gram of choline and 4 milligrams vitamin K. All rats received 3 milligrams alpha tocopherol in 0.05 cc ethyl laurate once a week, and 2,000 units of vitamin A and 400 units of vitamin D in corn oil twice a week. The basic diet contained 15 mg of iron per 100 Gm of diet of which 1 to 2 mg were iron impurities in the salt mixture and the remainder was in the purified calcium. Forty eight rats used in one experiment were divided into three equal groups. Group A received a high iron diet, 50 mg of iron as ferric phosphate being added to each 100 Gm of diet. Groups B and C received the basic low iron diet without iron supplement. The animals were kept on these diets for five weeks prior to the administration of radioiron. During the fifth week Group C animals were bled 2 per cent of their body weight on alternate days until the hemoglobin values were 6 to 9 Gm per cent (14 to 17 Gm per cent in Groups A and B). At the end of the fifth week all animals were starved for twenty four hours after which 1 mg of radioiron was given in water by stomach tube. The control animals received nothing.

In another experiment designed to eliminate the possible effects of twenty four hours of starvation sixteen rats were kept for four weeks on a high iron diet. Three days prior to the administration of 1 mg of radioactive iron as ferrous ammonium sulfate half the animals (A) were placed on a low iron diet for the remainder of the experiment while the other animals were kept on a high iron diet throughout (A). Food was not withheld even after the test meal was given. Animals were killed two, six and twenty four hours after the administration of the test dose. Control animals on the same diets were given no test dose of radioiron but were killed at corresponding times.

In order to determine absorption of iron by way of the lymphatics a 10 kilogram female terrier was prepared by inserting in the thoracic duct a plastic cannula which was carried through the skin incision. After two days the dog was given 57 mg of tagged iron

as ferrous ammonium sulfate by stomach tube in 300 cc of whole milk. The entire flow of thoracic duct lymph for the following six hours was collected in three parts. Blood samples were collected at three and five hours.

## RESULTS

Histochemically demonstrable iron will be referred to as visible iron. Radioactive iron demonstrated either by radioautographs or by Geiger counters will be referred to as radioiron. Control animals will be those handled exactly as their experimental counterparts except that they received no test dose.

In Tables I to III are tabulated the results of the experiments with guinea pigs. Inspection of these tables reveals that we were unable to confirm some of the observations of Gillman and Ivy regarding visible iron in guinea pigs. The distribution and amount of visible iron in the various organs evidently did not

change regularly in a cyclic form after a single iron meal under the present experimental conditions. In fact in view of the erratic variation in the experimental groups and the occurrence of the same range of variation in the control groups which had received no test meal of iron one would be led to doubt whether the test meal had any particular effect on the visible iron and would be inclined to believe that the visible iron must not have originated in the test meal.

The radioautographs and other tracer studies on these same animals indicate clearly that most of the visible iron did not originate in the test meal. There is no correlation between the distribution or amount of visible iron and the distribution or amount of radioiron. For example in the duodenal epithelium of a given animal the visible iron varied erratically from one villus to another, while the radioiron as shown by radioautographs, diminished smoothly from a maximum near the pylorus to a minimum in the proximal jejunum.

Similarly we were unable to confirm the observation that the formation of epithelial granular iron was reduced in anemic guinea pigs. In fact in Table II one notes that anemic animals tended to have more granules than normal animals. These findings throw some doubt on the suggestion of Gillman and Iv

that the epithelial granular ion is a morphologic expression of mucosal block. The tracer studies were interesting in this connection. Despite the wide variation in amount of visible granular ion in the duodenal epithelium the normal animals all absorbed about 15 per cent of the test meal iron while all anemic animals absorbed about 50 per cent.

The results of the guinea pig experiments were somewhat equivocal as to the role of the reticuloendothelial and lymphatic systems. The amount of visible ion in the lymph nodes, spleen and liver did not correlate with the amount of radionon. However, since most of the samples of these tissues were obtained more than two hours after the test meal and since absorption studies indicated that most of the absorption occurred in the first two hours, one could not exclude the possibility that the iron might already have entered the blood via the intestinal lymphatics and thoracic duct.

After efforts at quantitative collection of thoracic duct lymph in guinea pigs, rats and rabbits had failed the dog experiment was done for the purpose of determining to what extent iron entered the organism via the thoracic duct. The entire flow of thoracic duct lymph for six hours after the radionon test meal contained only 10.28  $\mu\text{g}$  of the test dose of iron. Assuming a blood volume equivalent to 8 per cent of body weight the blood samples collected at three and five hours indicated that the blood stream alone contained 104 and 196  $\mu\text{g}$  of the radionon respectively. In this one dog, absorbed iron was transported almost exclusively via the portal vein.

Having failed to confirm these findings of Callman and Ivy and having arrived at no clear understanding of the significance of visible ion we undertook the rat studies in the hope that careful control of dietary iron over relatively long periods might yield more illuminating results.

The results are tabulated briefly in Table IV. Visible ion occurred in much smaller amounts in rats than in guinea pigs although when present it occurred in the same form and same locations. There was no clear cut post prandial cycle and no correlation between visible ion and radionon. In a series

of unpublished experiments we were unable to relate the variation in amount and distribution of visible iron to the type of iron in the diet and, although a variety of ferrous and ferric compounds were tested as well as the stock guinea pig diet, we have been unable to increase the visible duodenal iron in rats to the levels seen in guinea pigs

In rats, as in guinea pigs, the amount of visible iron varied considerably even in groups having been maintained for weeks on the same carefully controlled iron intake. However, in twenty-six of forty-seven rats receiving high iron diet or test meal of iron within twenty-four hours before being killed, visible iron was demonstrated in the duodenal epithelium while it was absent in all of nine rats ( $A_1$  controls, B controls, and C controls) which had received a low iron diet for at least three days and no test meal. This suggests that considerable iron has been present in the diet within the last few days of life when visible iron is found in the duodenal epithelium. In twenty-nine of thirty-one rats given a high iron diet for several weeks, visible iron was present in the phagocytes of the duodenal stroma but was absent in twenty-three of twenty-five rats given a low iron diet throughout. Administration of a low iron diet for three days following several weeks of high iron diet (Group  $A_1$ ) did not result in the disappearance of the visible iron in the stroma. Apparently this stromal iron accumulates during periods of considerable iron intake and disappears more slowly than the epithelial iron during periods of low iron intake.

The amount of visible splenic iron in rats showed no relationship to the single test meal but was uniformly high in all rats on a high iron diet, moderate in rats on a low iron diet, and absent in anemic rats on a low iron diet. These findings are consistent with the widely accepted view that visible iron in the spleen is storage iron which reflects general levels of storage iron except in conditions characterized by excessive destruction of red cells.

#### SUMMARY

1 Combined histochemical, radioautographic, and tracer methods were used to study the absorption and distribution of single test meals of radioiron in guinea pigs, rats, and one dog.

2 The iron demonstrated histochemically in the duodenal mucosa, the mesenteric and cervical lymph nodes, liver, and spleen was derived largely from sources other than the single test meal. This visible iron did not undergo well-defined cyclic changes after a single iron meal. It accumulated over a period of days or weeks of continued intake of a diet containing considerable iron. It behaved more like storage iron than iron in transport.

3 The visible granular iron in the duodenal epithelium exerted no demonstrable effect on the amount of iron absorbed, and it did not appear to be a morphologic expression of mucosal block.

4 Most of the radioiron of the test meal traversed the duodenal epithelium rapidly. In one dog it was transported from the intestine via the portal vein—only insignificant amounts being found in thoracic duct lymph.

5 There was no evidence to indicate that the reticuloendothelial system participated directly in the absorption of iron from the intestine or transport of the absorbed iron from the intestine to the liver, blood, and other organs and tissues

## LABORATORY METHODS

---

### NEEDLE BIOPSY OF THE LIVER USING OXIDIZED CELLULOSE AND THROMBIN TO PREVENT HEMORRHAGE

H. L. CLAY, M.D., AND LEWIS DICKINSON, M.D.  
LOUISVILLE, KY

DURING the past fifty years needle biopsy of the liver has been performed for purposes of diagnosis and study of the etiology, pathogenesis, and altered physiology in various diseases of the liver. This relatively simple bedside procedure has been at times a helpful tool for the investigator in attempting to evaluate different regimes of therapy and various liver function tests. Needle biopsy offers several advantages over other methods of obtaining material for microscopic study. A needle biopsy sample of liver tissue can be immediately fixed, stained, and studied without the necessity of attempting to evaluate the autolytic changes that may be encountered at times in post-mortem material. Another advantage of needle biopsy is that repeated studies of the same patient's liver can be carried out at varied intervals, whereas it is not usually feasible to repeat laparotomies merely to examine microscopically sections of the liver. In some instances patients critically ill with cancer have been spared the discomforts of an unnecessary exploratory laparotomy because it has been possible to confirm the presence of hepatic metastasis by means of microscopic examination of material from a diagnostic needle biopsy of the liver. Since this procedure at times offers so much from a diagnostic and clinical standpoint, one might wonder why there have been only about 2,000 instances of its use reported in the literature during the past half century. Examination of the mortality and complications following the use of this procedure as reported<sup>1-11</sup> readily reveals the reason for the lack of a more general interest and application of needle biopsy of the liver. It is noteworthy that eleven of fourteen deaths reported in the literature as resulting from needle biopsy were due to hemorrhage and three were from peritonitis.

#### METHOD

The method which we used in our first 140 biopsies, 119 of which have been reported,<sup>12</sup> has been used extensively in this country and described in previous reports.<sup>4,7,9,12</sup> The Vim Silverman needle was employed through an anterior subcostal approach. The procedure which we are now using and have employed during our last eighty five biopsies involves the use of the Vim Silverman needle in conjunction with a trocar, plunger, and cartridge for oxidized cellulose\* (see Fig. 1).

---

From the Department of Medicine, University of Louisville School of Medicine.

Received for publication Oct. 16, 1948.

\*The liver biopsy instruments used in this study were made for us by Mr. Harold Breeding, Instrument Technician, Department of Physiology, University of Louisville School of Medicine, and may be procured from Mr. Breeding.

Fig 1—Needle biopsy technique with modified Vim Silverman needle trochar cartridge for oxidized cellulose and plunger (See Method)

Bleeding clotting and prothrombin times are determined prior to biopsy and the patient is given intramuscular sodium phenobarbital sedation. With the patient lying on his back the abdomen is prepared carefully with Merthiolate and alcohol and draped with sterile towels. The skin of the abdominal wall down to and including the peritoneum is then carefully infiltrated with novocain. A 2 to 3 mm incision is made in the skin with a No. 11 Bard Parker blade to facilitate the introduction of the trochar and needle. For an enlarged liver the site usually selected is about 2 cm to the right of the midline and just below the costal margin but this varies with the individual case and depends upon the location of palpable nodules or special areas that one might desire to biopsy. The Vim Silverman needle locked inside the trochar by a set screw (as shown in *A* Fig 1) is introduced through the skin and down into the liver until the entire bevel of the Silverman needle is beneath the liver capsule. The stylet is removed and the cutting blades are introduced through the Silverman needle 17 cm into the liver substance (as shown in *B* Fig 1). The cutting blades are then held firmly in place while the trochar and Silverman needle are also pushed down over the cutting blades 17 cm into the liver tissue thus shearing off the tissue protruding from the sides of the cutting blades. The set screw on the trochar is next released and the Silverman needle and cutting blades containing the biopsy are rotated through 60 degrees and removed together from the trochar. At this point the tip of the trochar is still 1.7 cm down into the liver substance at the base of the biopsy site (as shown in *C* Fig 1). The cartridge (shown in *D* Fig 1) containing oxidized cellulose (Oxycel or Gelfoam) which has been made pliable by soaking in thrombin solution is placed into the trochar and the plunger (shown in *F* Fig 1) is pushed down through the cartridge and trochar forcing the cellulose plug into the base of the biopsy tract in the liver. As this is being done the trochar is withdrawn from the liver leaving the biopsy site packed with a plug of oxidized cellulose and thrombin (as shown in *F* Fig 1). As a further adjunct to the control of bleeding a small piece of gauze is placed over the skin incision and firm pressure is applied directly over the biopsy site with the gloved thumb for approximately five minutes.

The biopsy tissue is removed from the cutting blades and is immediately put into the fixative, or, if glycogen determinations are to be made, is immediately immersed in potassium hydroxide in a weighed container. The patient is kept as flat as possible for six to eight hours after the biopsy and is allowed out of bed in eighteen to twenty four hours if there are no complications apparent or other contraindications for his being ambulatory.

#### RESULTS

In our first 119 biopsies without the use of oxidized cellulose and thrombin, we had the following complications. Symptoms of shock in three instances (mild and readily overcome, plasma being used in only one case), mild bile peritonitis in two instances. In our present series of eighty-five cases using oxidized cellulose and thrombin, we have had no untoward symptoms or signs of any complication.

#### DISCUSSION

The liver biopsy method outlined in this report was developed for the primary purpose of reducing the danger of hemorrhage which has heretofore been the chief cause of mortality associated with this procedure. Proper selection of cases is still necessary, and care in directing the needle is also very important, because perforation of a viscus with resultant peritonitis may occur. Furthermore, it is felt that this procedure will certainly not prevent arterial hemorrhage as in the case reported by Hoffbauer<sup>7</sup>, consequently, care must still be used in observing the patients after this procedure.

#### SUMMARY

A method of employing oxidized cellulose and thrombin which may aid in preventing fatal hemorrhage from the liver following needle biopsy is herein presented.

## DETECTION OF BROMATE IN BLOOD AND URINE

A L DUNN, PH D, AND A R MCINTYRE, M D, PH D  
OMAHA, NEB

WITH the widely prevalent use of bromate solutions in conjunction with hair waving kits of various manufacturers a need has arisen for a rapid qualitative test for bromate ion in blood and urine to establish with surety the presence of bromate in those rare instances in which accidental ingestion is suspected so that appropriate therapeutic measures can be instituted. A test is presented which has high sensitivity and utilizes reagents readily available in any hospital laboratory. Such cases of poisoning are rare, but the frequency of cases in which bromate poisoning is suspected has increased recently. This test will prove of value in making a positive diagnosis.

One of the early uses of an azo dye such as methyl orange in a qualitative analysis for a halate was made by Besemann<sup>1</sup>. Korenman<sup>2</sup> found that the decolorization of methyl orange by bromate ion proceeded much more rapidly than by chlorate, iodate and other oxidizing anions and based a qualitative test for bromate on this decolorization by an acidified solution containing bromate ion. He claimed a sensitivity of 14 gammas in 2 cc of solution. Sarudi<sup>3</sup> evolved a volumetric determination of bromates using methyl orange as an indicator. A comparison of volumetric analyses for bromate using the iodometric technique and using methyl orange as the indicator was made by von Stetina<sup>4</sup> who found that methods using methyl orange as an indicator were in good agreement with the iodometric technique.

Korenman also established the quantities of other substances which obscure the decolorization of dilute methyl orange by 20 gammas of potassium bromate in weak acid solution. A summary of his figures is given in Table I.

As a part of the development of the following procedure, a careful evaluation of some of the commonly available azo dyes was made. Their hues and intensities and relative sensitivities to bromate were studied. See Table II. Methyl orange in the dilution used and in acid medium has a pale pink color which is difficult to see in urine and impossible to use with plasma from blood in which the slightest hemolysis has occurred. Bismark brown has a weak yellow brown color in dilute solution and hence is useless when determining bromate in urine. Congo red and tripan blue are more satisfactory but neither gives as strong a color in the dilution used as does Evans blue. Of the dyes investigated Evans blue was superior in hue and intensity and was equal to any of the others in sensitivity to bromate. A very sharp clean cut test could be obtained with concentrations of potassium bromate of 10 gammas per cubic centimeter of tested fluid. Of all the substances having any likelihood of being

From the Department of Physiology and Pharmacology, University of Nebraska College of Medicine.

This work was supported in part by a grant from The Toni Company, Chicago, Ill.

Received for publication Nov. 5, 1948.

TABLE I

(By its rapidity in decolorizing 2 drops of 0.015 per cent methyl orange in weak acid, 20 gammas of potassium bromate can be detected in the presence of the indicated amounts of the substances listed below. Of the substances tested, nitrite is shown to be the most likely to interfere. Korenman<sup>2</sup>)

KIO <sub>3</sub>	40 mg	(KBrO <sub>3</sub> KIO <sub>3</sub> = 1 2,000)
KClO <sub>3</sub>	20 mg	(KBrO <sub>3</sub> KClO <sub>3</sub> = 1 1,000)

NaNO <sub>2</sub>	300 γ	(KBrO <sub>3</sub> NaNO <sub>2</sub> = 1 15)
NaCl	400 mg	(KBrO <sub>3</sub> NaCl = 1 20,000)
KBr	200 mg	(KBrO <sub>3</sub> KBr = 1 10,000)
(NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub>	200 mg	(KBrO <sub>3</sub> (NH <sub>4</sub> ) <sub>2</sub> S <sub>2</sub> O <sub>8</sub> = 1 10,000)

present in the blood or urine, only nitrite interfered by shifting the color of the dye from blue to violet or, in higher concentrations, by decolorizing it. This was to be expected since Korenman's figures show that nitrite ion, among the substances he tested, approached nearest to bromate in its power of decolorizing

methyl orange The well known reaction between nitrous acid and primary amines can be utilized to destroy nitrite, simply by the addition of an excess of urea to the acidified solution to be tested When very minute quantities of bromate are present, the addition of urea slows the decolorization of the dye but does not interfere with the test

#### PROCEDURE

To 2 c.c. of blood plasma or urine to be tested add 1 c.c. of 3 or 4N HCl If plasma is used, centrifuge after adding the acid to throw down the proteins Add 0.1 c.c. or 2 drops of 0.01 per cent Evans blue in water solution Immediate fading of the blue color shows the presence of bromate If nitrite is suspected add 0.25 gm. of urea and wait for the evolution of nitrogen to cease before adding the dye When bromate is present in amounts corresponding to 1 mg. per cent  $\text{KBrO}_3$ , the time required to decolorize the dye in the presence of urea is lengthened to ten or fifteen seconds

#### SUMMARY

A simple and rapid method for the detection and confirmation of the presence of bromate in blood or urine has been described The method is based on the selective decolorization of an azo dye Evans blue by bromate ion

# THE USE OF AZOALBUMIN AS A SUBSTRATE IN THE COLORIMETRIC DETERMINATION OF PEPTIC AND TRYPTIC ACTIVITY

RUDOLPH M. TOMARELLI, PH D, JESSE CHARNEY, M S, AND  
MARY LORD HARDING, M N  
PHILADELPHIA, PA

THE coupling of a protein with a diazotized aryl amine will produce a chromophoric derivative. Such an azoprotein may be precipitated from solution by trichloroacetic acid to yield a colorless filtrate. If the azoprotein solution is subjected to proteolytic digestion, colored reaction products are formed which are soluble in trichloroacetic acid solution. The intensity of color in the trichloroacetic acid filtrate of the digested substrate is a function of the proteolytic activity of the enzyme solution. These findings have served as a basis for a colorimetric method for the determination of the proteolytic activity of duodenal juice<sup>1</sup>. Sulfanilamide-azocasein, the substrate used, being soluble only in alkaline solution, could not be used for the determination of peptic activity. The present publication reports the preparation of an azoalbumin which is soluble in both alkaline and acid solution and therefore permits the colorimetric method to be adapted to the analysis of gastric as well as duodenal juice.

## EXPERIMENTAL

*Preparation of Sulfanilic Acid Azoalbumin* Solution A 50 Gm of bovine plasma albumin\* are dissolved in 1 l H<sub>2</sub>O. Ten grams NaHCO<sub>3</sub> suspended in 100 ml H<sub>2</sub>O are added with stirring. Solution B 0.025 mole sulfanilic acid is dissolved in 200 ml H<sub>2</sub>O containing 0.025 mole NaOH (50 ml of 5.0N), 0.025 mole NaNO<sub>2</sub> added. Solution stirred and 0.05 mole (100 ml of 5.0N) HCl added. Solution stirred two minutes and 0.05 mole NaOH (100 ml 5.0N) added to stirred solution. Solution stirred for five seconds and added at once to Solution A with vigorous stirring.

Material stirred five minutes and dialyzed against cold tap water overnight. The dialyzed solution is then lyophilized. The azoalbumin is a red orange compound with an absorption maximum at 440 to 450 mμ (Fig 1). The color concentration relationship of azoalbumin follows Beer's law (Fig 2). This is fortunate in that in the calculation of enzyme activity, optical density values may be substituted for substrate concentrations. The azoalbumin is soluble in the pH range below 3 and above 5.

*Digestive Juice* The gastric or duodenal juice sample is centrifuged at about 1,500 rpm for ten minutes and the sample is taken from the relatively homogeneous middle layer. Duodenal juice samples are diluted 1:100 with 0.5N ammonium hydroxide ammonium chloride buffer of pH 9.5. Gastric juice samples are diluted 1:20 with 0.2N hydrochloric acid sodium citrate buffer of pH 1.6.

From the Nutritional Service of the Department of Pediatrics and the Gastrointestinal Section of the Medical Clinic of the University of Pennsylvania Medical School and the Wyeth Institute of Applied Biochemistry.

Presented at the Miniature Meeting of the Philadelphia Section of the American Chemical Society Jan 22 1948.

Received for publication Dec 1 1948.

\*The preparation used was bovine plasma albumin Fraction V Armour Company Chicago.  
† Other albumins may be used.

Fig 1—Absorption curve of sulfanilic acid azoalbumin (0.12 mg per milliliter)

Fig —Color concentration relationship of azoalbumin

**Substrate Solution** The azoalbumin is dissolved in the buffer appropriate to the determination at a concentration of 25 mg per milliliter

**Procedure** The details of the assay procedure have been reported in an earlier publication.<sup>1</sup> Each determination is set up in duplicate. One milliliter of substrate solution is pipetted into a test tube, 1 ml of the diluted enzyme sample is added and the mixture digested for thirty minutes at 38° C. The digestion is stopped and undigested substrate removed from solution by the addition of 8 ml of 5 per cent trichloroacetic acid

Fig 3—Relationship of proteolytic activity of duodenal juice to time of digestion

Fig 4—Relationship of proteolytic activity of gastric juice to time of digestion

The contents of each tube are filtered through paper. To a 5 ml aliquot of the filtrate are added 5 ml of approximately 0.5N NaOH and color intensity is read on a photoelectric colorimeter (440 mμ). A substrate blank is prepared by adding 1 ml of buffer to 1 ml of substrate solution and treating the tube in the same manner as the samples. No blank need be run for the enzyme solution since the final dilution in the case of duodenal juice is 1:2,000, and 1:400 for gastric juice.

The activity of the juice is expressed in terms of the velocity constant of the enzymatic reaction,  $K = \frac{1}{t} 2.3 \log \frac{C_1}{C}$ , where  $C_1$  and  $C$  are initial and final protein concentrations respectively after  $t$  minutes of digestion.

Since the color concentration relationship of azoalbumin and its digestion products obeys Beer's law, optical density values may be substituted for  $C$  values. The initial concentration,  $C_1$ , is determined by adding 5 ml of 0.5N NaOH to a 5 ml aliquot of a 1:200 dilution of the substrate solution and then reading the color of the final solution. This optical density value is multiplied by twenty to yield the  $C$  value, since the undigested sample is diluted twenty times more than the filtrate samples. The  $C_2$  value is determined by subtracting the optical density of the trichloroacetic acid filtrate from the  $C_1$  value. This is permissible since a solution of azoalbumin which is completely digested (no trichloroacetic acid precipitate) has the same color intensity as an undigested sample.

The velocity constant is calculated for the diluted solution and multiplied by the dilution factor to obtain the reaction constant for the undiluted juice.

Fig 5—Relationship of proteolytic activity to the enzyme concentration of duodenal juice

*Relationship of Proteolytic Activity With Time of Digestion*—The velocity constant may be used in expressing enzyme activity only if the digestion rate of azoalbumin fulfills the requirements for a monomolecular reaction, i.e.,  $\log \frac{C_1}{C}$  should be directly proportional to time. By digesting samples of the substrate for varying periods of time with a dilution of the digestive juice the time activity relationships for duodenal juice (Fig 3) and for gastric juice, (Fig 4) were obtained. The rectilinearity of the relationship for each of the juices is in accordance with monomolecular reactions.

*Relationship of Enzyme Concentration and Activity*—The velocity constant of an enzyme reaction is a function of enzyme concentration. The relationship between enzyme activity  $\log \frac{C_1}{C}$  and enzyme concentration proved to be rectilinear in the digestion of azoalbumin with duodenal juice and with gastric juice, Figs 5 and 6. A similar relationship was demonstrated with a

commercial trypsin concentrate\* This direct proportionality of enzyme activity with the dilution is fortunate in that it permits recalculation to original juice or enzyme solution activity merely by multiplying the velocity constant by the dilution factor A similar study with an aqueous extract of papaya powder fortified with cysteine did not give a rectilinear relationship except

Fig 6—Relationship of proteolytic activity to the enzyme concentration of gastric juice

in regions of extreme dilution This nonconformity may result from the presence in the crude preparation of inhibitors which are effective at the higher concentration, or perhaps the mode of attack by papain on the azo protein differs from that of the enzymes of gastric and duodenal juice

#### DISCUSSION

The selection of albumin for the preparation of the azoprotein substrate permits the colorimetric method for proteolytic activity to be used for gastric as well as duodenal juice With azoalbumin as the substrate, proteolytic activity may be determined for any enzyme that is active in the pH regions above 5 and below 3 The colorimetric method has proved readily adaptable to the routine testing of clinical samples It is simple, sensitive, and has shown a high degree of reproducibility The substrate is easily prepared and solutions are relatively immune to bacterial contamination Since the substrate is soluble, the method has a definite advantage in that the rate of digestion is not influenced by particle size The color concentration relationship of azo albumin and its digestion products adheres to Beer's law, thus eliminating the necessity for nomographs The color is stable and chromogenic reagents are not required for its development Although the details of the cleavage of

\*Fisher Scientific Company

azoalbumin have not been studied, the method appears to be a true measure of proteolytic activity. The appearance of color in the trichloroacetic acid filtrate necessitates cleavage of the peptide bond, since the chromophoric grouping requires an intact diazotized amino acid or peptide fragment. Furthermore, comparative studies have shown that the colorimetric method has given results in good agreement with those obtained by the method of Riggs and Stadie.

#### SUMMARY

A colorimetric method for the determination of the proteolytic activity of gastric and duodenal juice is described. The digestion of a solution of azoalbumin by a dilution of the digestive juice produces colored reaction products which are soluble in trichloroacetic acid. The color intensity of the trichloroacetic acid filtrate of the digested substrate solution is a function of proteolytic enzyme concentration.

# A HEMATOLOGIC SLIDE RULE FOR CALCULATING THE CORPUSCULAR CONSTANTS

WILLIAM R. BEST, M.D.  
CHICAGO, ILL.

SINCE Wintrobe<sup>1</sup> first demonstrated a knowledge of the corpuscular constants to be of aid in evaluating the anemias, clinicians and technicians have struggled with the necessary calculations. The time-honored and most tedious approach is through a process of long division, repeating the calculations three to arrive at mean corpuscular volume, mean corpuscular hemoglobin, and mean corpuscular hemoglobin concentration respectively. Those adept with the slide rule may shorten this process somewhat. Wintrobe<sup>6</sup> presents a nomogram by R. E. Mason which is easily reproduced, is reasonably accurate, and delineates normal ranges for the corpuscular constants. Its disadvantages are those of all nomograms, namely, the difficulties of deciphering which scales are used for various purposes and of fixing and maintaining a ruler on given points of widely separated scales. Whillans<sup>3</sup> has devised a circular slide rule having two scales with which the standard corpuscular constants as well as volume, color, and saturation indices may be determined. Allowance may be made for hemoglobin readings in per cent and for use of potassium oxalate alone as anticoagulant. This instrument is very useful but is not as simple nor as complete in supplementary information as is the one herein described. Recently a pharmaceutical house\* has distributed a linear slide rule which will aid in various minor hematologic calculations as well as the color index, but it is not concerned with the corpuscular constants.

## DESCRIPTION

The present calculator (Fig. 1) is essentially a circular slide rule having three revolving, concentric disks graduated with appropriate segments of logarithmic scales corresponding to *C* and *CI* scales on the standard slide rule. These, together with a transparent indicator, pivot about a central rivet. The method of manipulation is simple and is clearly explained on the rule itself. Ranges of adult normal persons for red count, hemoglobin, hematocrit, and the three corpuscular constants are indicated according to the values of Wintrobe<sup>6</sup>. Approximately 85 per cent of normal persons should fall within these ranges. A scale for conversion of per cent to grams as well as scales for volume, color, and saturation indices corresponding to respective corpuscular constants is included. The latter are based on values of 5.0 million for erythrocytic count, 43.2 per cent for hematocrit, and 14.5 grams for hemoglobin.<sup>6</sup> Approximate

---

  
ERRATUM

In the article by Chang and Hou Cold Hemagglutinin Test by a Slide Method, in the November 1948 issue of the Journal the fifth line of the Discussion, p 1449, should read ' in Table III cannot be explained by the difference in the method of examining ' ,

TABLE I RANGE OF EXPECTED ERROR OF RED COUNT USING ONE PIPETTE AND ONE COUNTING CHAMBER, ACCORDING TO VARIOUS ESTIMATES AND CALCULATIONS

TRUE ERYTHROCYTIC COUNT	EXPECTED RANGE OF ERROR		
	BERLSON	WINTROBE	PRESENT RULE
5,000,000	800,000	200,000	400,000
2,000,000	370,000	200,000	150,000

an accuracy of  $\pm 2.3$  per cent. Improperly standardized instruments may vary as much as 20 per cent. The error of the eye in matching colors in visual hemoglobinometers has been stated to be 10 per cent and is probably greater in many cases. A hematocrit after centrifugation at 3,000 r.p.m. for thirty minutes should give an accuracy of  $\pm 0.5$  per cent. In a well-regulated laboratory, Wintrobe<sup>6</sup> states that the corpuscular constants should not vary more than  $\pm 2.5$  cubic microns for M.C.V.,  $\pm 1.0$  micromicrograms for M.C.H., or  $\pm 0.8$  per cent for M.C.H.C. All of these expected ranges of variation have been roughly indicated on the calculator.

## DISCUSSION

In checking the calculator against values obtained by long division we not infrequently have found errors of several points in the long division process.

Table II illustrates the saving in steps, and hence of time, in determining the corpuscular constants by the present method as against the other methods reviewed.

TABLE II STEPS REQUIRED IN CALCULATING CORPUSCULAR CONSTANTS ACCORDING TO VARIOUS METHODS

TECHNIQUE	NUMBER OF STEPS
Long division	30
Slide rule	9
Nomogram	9
Whillans' rule	9
Present calculator	6

Norris and Vogan<sup>2</sup> have proposed a chart showing relationship of red count, hemoglobin, and hematocrit for use in checking the accuracy of laboratory procedures against each other in routine determinations on patients without anemia and on otherwise healthy persons who have suffered acute blood loss or hemoconcentration. The calculator herein described may be used for the same purpose by setting the triangular pointers for the corpuscular constants to the 10 mark on the corresponding hematologic indices. Individual determinations of the three primary values (red count, hemoglobin, and hematocrit) for a patient fitting the foregoing description which are significantly out of alignment with the other two primary values may be considered in error.

## SUMMARY

A new, simplified, circular slide rule for calculation of the corpuscular constants and related hematologic indices is presented. Ranges of adult normal persons as well as expected ranges of variation in determinations are clearly indicated. A method of using the instrument for checking laboratory procedures against each other is outlined.

# RESPONSE OF LINGUAL MANIFESTATIONS OF PERNICIOUS ANEMIA TO PTEROYLGLUTAMIC ACID AND VITAMIN B<sub>12</sub>

JAMES F. SCHIFF, M.D. AND R. W. RUNDLES, M.D.  
DURHAM, N. C.

ALTHOUGH the therapeutic effectiveness of synthetic pteroylglutamic acid in the majority of patients with pernicious anemia has been satisfactory, shortcomings have been observed. At the beginning of therapy, reticulocytosis although prompt is often suboptimal. The rise in red cell count is usually slower than with liver extract. Macrocytosis may persist for months, and during maintenance therapy the blood values may even decline.<sup>4, 10, 11, 13, 17, 19, 20</sup> While some patients with the neurologic manifestations of pernicious anemia may show improvement early in the course of pteroylglutamic acid therapy,<sup>5, 8, 9</sup> the failure of this compound in doses of 25 to 20 mg. per day to protect patients against neurologic relapse has been of great concern.<sup>11, 13, 14, 17, 21, 24, 27, 28, 30, 31</sup>

The effect of pteroylglutamic acid on the third important clinical manifestation of pernicious anemia, that of atrophy and inflammation of the lingual mucosa, has received less study, but in some cases at least it appears to be unsatisfactory.<sup>11, 13, 15</sup> The purpose of this paper is to report additional patients with the lingual manifestations of pernicious anemia who were treated with pteroylglutamic acid. In some the response was good, in others poor. Two developed severe lingual relapses while taking 30 to 50 mg. per day of the compound. The lingual abnormalities in the latter cases responded to injections of vitamin B<sub>12</sub>,<sup>6</sup> as promptly as did the lingual manifestations in patients with pernicious anemia who had had no previous treatment.

Each of the following patients exhibited one or more of the clinical manifestations of pernicious anemia. All of them had histamine refractory gastric achlorhydria. Other complicating diseases were not present. Details of the neurologic disease in some cases will be reported later.

The following patient was one of two in whom pteroylglutamic acid therapy produced a rapid restoration of normal lingual mucosa. The tongue remained normal and there was neurologic improvement in spite of an incomplete hematologic remission.

W. P. 68799. This 55-year-old mulatto admitted to Duke Hospital on Aug. 15, 1946, first developed the lingual and anemic manifestations of pernicious anemia in 1936. He responded well to injections of liver extract but, being indifferent about maintenance therapy, suffered at least three relapses, one with considerable neurologic damage. For at least six

From the Department of Medicine, Duke University School of Medicine and the Hematology Laboratory, Duke Hospital.

The pteroylglutamic acid, Foltec, was kindly supplied by Dr. Stanton M. Hardy of Lederle Laboratories.

The vitamin B<sub>12</sub> was supplied through the courtesy of Dr. Augustus Gibson, Merck & Co., Inc.

This work was supported by a grant from the Anna A. Hanes Fund.

## NOTE ON A SUBSTANCE TO SEAL PLETHYSMOGRAPHIC CUPS OF THE BURCH-WINSOR TYPE

C W ROBERTSON, M D , AND R H SMITHWICK, M D  
BOSTON, MASS

A MINOR problem in the use of a digit plethysmograph in which an airtight seal must be obtained between a plastic or glass cup and the digit is the choice of a sealing compound. The Burch-Winsor plethysmograph\* is an example of this type of apparatus. There are at the present time approximately eighty of these machines in use. Our experience with a new type of sealing compound therefore is considered worth reporting in the hope that it may help others in the use of this type of instrument.

The sealing compound furnished with the machine is a mixture of printers' compound and ordinary glue. Various proportions of these two substances yield products with slightly different physical characteristics with regard to melting points, rubberiness, etc. All combinations, however, have the disadvantages of (1) being water soluble (2) requiring their use in a heated state, (3) being very tacky and difficult to manage if not applied immediately after transfer from the heating bath. Being water soluble makes the compound unstable when the digit is perspiring, with dilution of the compound at the skin surface and consequent instability of the cups or even loss of seal. The last two disadvantages are of particular importance in dealing with digits which are surviving on impaired or collateral circulation entirely. In such patients use of a melted sealing compound introduces the likelihood of producing a burn in tissues that are of borderline viability.

In attempting to find a substitute, several of the commercially available cements—rubber glues, liquid adhesives—were tried. The compound which was found to be most useful was a substance located at Sears Roebuck and Company called Kalk-Koid†. This was originally designed for a number of things including repair of windows, bathrooms, sealing boats, etc. The compound was tried and is at the present time being used as follows in our laboratory. The digit is measured by placing it into a gentian solution until it has displaced 5 c c of solution. A ring of the compound is then placed around the finger at the top of the stain and the cup then placed over the digit to the level of the stain. A seal is obtained by working the compound around the cup with the fingers. Runs of the same digit using the commercial printers' compound-glue jelly and the Kalk-Koid at different times have shown no significant change in the pulse amplitude so that we feel the Kalk-Koid does not cause significant venous occlusion and consequent change in digit volume. This substance has shown no tendency to change consistency at the range of temperatures which we employ in our surface temperature laboratory, i e, 65° to 85° F, and it seems to be quite insoluble in water.

deficiency Dietary treatment was attempted without notable success Six months before admission she became markedly forgetful At that time her tongue again became red and sore Numbness and tingling in her extremities became worse Two months before admission confusion, weakness and gross unsteadiness in walking became severe enough to confine her to bed.

Examination showed a confused poorly oriented, inattentive woman barely able to move her legs in bed and just able to sit up alone The tongue was beefy red and entirely smooth except along the margins where remnants of filiform papillae were just visible Neurologic examination showed evidence of severe peripheral neuropathy, posterior and lateral column disease The hemoglobin was 13.5 grams per 100 c.c. RBC 4,020,000 WBC 19,000 hematocrit 40.8 per cent and average cell volume 101 cubic micra

Pteroylglutamic acid was given by mouth for four weeks in a daily dose of 100 milligrams After seven days the color of the tongue was nearly normal and regenerating filiform papillae were easily visible During the second week the patient became stronger and clearer mentally but then she appeared to get worse The filiform papillae which had remained stubby became shorter and the color of the tongue became a deeper red The red cell count fell to 3,630,000 and the hematocrit to 35.1 per cent There was no change in her condition after five days of vitamin B therapy 30 mg of thiamin 15 Gm. para-aminobenzoic acid 10 mg riboflavin 300 mg niacin 50 mg calcium pantothenate and 5 mg pyridoxine being given daily It was then considered advisable to begin intensive liver extract therapy There was little apparent improvement during the first month except for regrowth of lingual papillae and rise in blood values After two months of liver therapy the patient's strength and motor ability began to improve steadily The hematologic values and the appearance of the tongue became normal and remained so At the end of twelve months of liver therapy she was able to do all ordinary activities at home with little motor handicap Her mental condition improved until she was about as well as before her illness Neurologic examination continued to show the expected residuals of posterior and lateral column disease

The following two patients treated with pteroylglutamic acid developed distinct lingual relapses during the third month of therapy in spite of satisfactory hematologic and neurologic responses

**Case D C-33368** This 30 year old married postal clerk was admitted to Duke Hospital on April 26 1948 Five years previously he had developed a 'red and slick' tongue that despite vitamin B therapy became sore from time to time She became chronically weak and nervous and worried intensely about minor incidents She was afraid of "losing her mind" Nine weeks before admission to the hospital her tongue became particularly sore A few days later she found it difficult to control the movements of her feet Her legs began to feel stiff and tight Her memory deteriorated and she became confused For several days before her hospital admission she was confined to bed by extreme weakness

Examination showed a confused and apprehensive young woman She made many mistakes in doing mental arithmetic The tongue was carlet in color had no coat and in the midsomum there were no visible papillae She was unable to get out of bed without assistance and could not walk without support from both sides The tendon reflexes in upper and lower extremities were hyperactive The cutaneous senses were severely blunted below the knees There was but little ataxia with the heel to shin test The vibratory sense was absent below the costal margin The plantar responses were flexor There was sustained ankle clonus more pronounced on the left side.

The hemoglobin was 12.0 grams per 100 c.c. RBC 3,300,000 WBC 8,750 hematocrit 34 per cent and the average cell volume 101 cubic micra Examination of the bone marrow showed early evidence of megaloblastic cell development

Experimental therapy with pteroylglutamic acid was started under close observation During the first month the patient was given 100 mg of the acid daily by mouth and for the next two months 50 mg daily The red cell count rose to 4,100,000 during the first month

months before his hospital admission he had again had no antianemic therapy. For three months his legs had been too weak to permit him to work. Numbness and tingling had developed about his feet and his gait had been drunken. His tongue had not felt sore.

On admission the tongue was reddish pink in color and not coated. The filiform papillae were so short as to be scarcely visible. Neurologic examination showed evidence of peripheral nerve and posterior column disease. The red cell count was 2,620,000, hemoglobin, 10.5 grams, hematocrit, 32.6 per cent, and the average cell volume, 124 cubic microns.

Fig 1—A, Photograph of a red smooth tongue in a patient with previously untreated pernicious anemia. B, Photograph of same tongue seven days later showing regeneration of normal lingual papillae with administration of 100 mg pteroylglutamic acid daily.

Pteroylglutamic acid was given in a dose of 75 mg daily by mouth. After six days of therapy, the tongue had become pale pink in color and faintly coated. Filiform papillae had grown to nearly normal height. The pteroylglutamic acid was maintained during the next five months, at first 30 mg per day and then 15 milligrams. The neurologic symptoms of recent onset subsided and the patient returned to work. The appearance of his tongue remained normal. The red blood count did not rise to over 3,560,000, however, and macrocytosis persisted. Because of the persistent macrocytosis, liver extract was recommended as permanent maintenance therapy.

The following patient was one of four with pernicious anemia in whom pteroylglutamic acid failed to produce an adequate lingual response. Liver extract was more effective finally in correcting the lingual and other manifestations of the disease.

E W, B 87399. This 68 year old white woman, admitted to Duke Hospital on Aug 28, 1946, had enjoyed good general health with the exception of a mild convulsive disorder of six years' duration. Three or four years before her hospital admission her tongue became intermittently red and sore. Numbness and tingling developed in her hands and feet. These symptoms led to the diagnosis of pellagra, although she was a hearty eater, her selection of food was reasonably good, and no other member of her family had symptoms of nutritional

deficiency Dietary treatment was attempted without notable success Six months before admission she became markedly forgetful At that time her tongue again became red and sore Numbness and tingling in her extremities became worse Two months before admission, confusion, weakness and gross unsteadiness in walking became severe enough to confine her to bed

Examination showed a confused poorly oriented inattentive woman barely able to move her legs in bed and just able to sit up alone The tongue was beefy red and entirely smooth except along the margins where remnants of filiform papillae were just visible Neurologic examination showed evidence of severe peripheral neuropathy, posterior and lateral column disease The hemoglobin was 13.8 grams per 100 cc RBC, 4,020,000, WBC 19,000, hematocrit, 40.8 per cent and average cell volume 101 cubic micra

Pteroylglutamic acid was given by mouth for four weeks in a daily dose of 100 milligrams After seven days the color of the tongue was nearly normal and regenerating filiform papillae were easily visible During the second week the patient became stronger and clearer mentally but then she appeared to get worse The filiform papillae which had remained stubby became shorter and the color of the tongue became a deeper red The red cell count fell to 3,630,000 and the hematocrit to 38.0 per cent There was no change in her condition after five days of vitamin B therapy 30 mg of thiamin, 15 Gm para aminobenzoic acid, 10 mg riboflavin 300 mg nicotin 50 mg calcium pantothenate and 5 mg pyridoxine being given daily It was then considered advisable to begin intensive liver extract therapy There was little apparent improvement during the first month except for regrowth of lingual papillae and rise in blood values After two months of liver therapy the patient's strength and motor ability began to improve steadily The hematologic values and the appearance of the tongue became normal and remained so At the end of twelve months of liver therapy she was able to do all ordinary activities at home with little motor handicap Her mental condition improved until she was about as well as before her illness Neurologic examination continued to show the expected residuals of posterior and lateral column disease<sup>2</sup>

The following two patients treated with pteroylglutamic acid developed distinct lingual relapses during the third month of therapy in spite of satisfactory hematologic and neurologic responses

V D, C-33368 This 30 year old married postal clerk was admitted to Duke Hospital on April 26 1948 Five years previously she had developed a 'red and slick' tongue that despite vitamin B therapy became sore from time to time She became chronically weak and nervous and worried intensely about minor incidents She was afraid of "losing her mind" Nine weeks before admission to the hospital her tongue became particularly sore A few days later she found it difficult to control the movements of her feet Her legs began to feel stiff and tight Her memory deteriorated and she became confused For several days before her hospital admission she was confined to bed by extreme weakness

Examination showed a confused and apprehensive young woman She made many mistakes in doing mental arithmetic The tongue was scarlet in color had no coat and in the midsomum there were no visible papillae She was unable to get out of bed without assistance and could not walk without support from both sides The tendon reflexes in upper and lower extremities were hyperactive The cutaneous senses were severely blunted below the knees There was but little ataxia with the heel to shin test The vibratory sense was absent below the costal margins The plantar responses were flexor There was sustained ankle clonus more pronounced on the left side

The hemoglobin was 12.0 grams per 100 cc RBC 3,300,000 WBC 8,750, hematocrit, 34 per cent and the average cell volume 101 cubic micra Examination of the bone marrow showed early evidence of megaloblastic cell development

Experimental therapy with pteroylglutamic acid was started under close observation During the first month the patient was given 100 mg of the acid daily by mouth and for the next two months 50 mg daily The red cell count rose to 4,100,000 during the first month

of therapy, the hematocrit to 42 per cent. After nine weeks the blood values and cell indices were entirely normal and remained so. During the first three months of treatment, her strength and ability to walk improved until she could do all of her housework without difficulty. Neurologic examination showed improved motor ability, less cutaneous sensory defect, and less pronounced ankle clonus. She gained eleven pounds in weight.

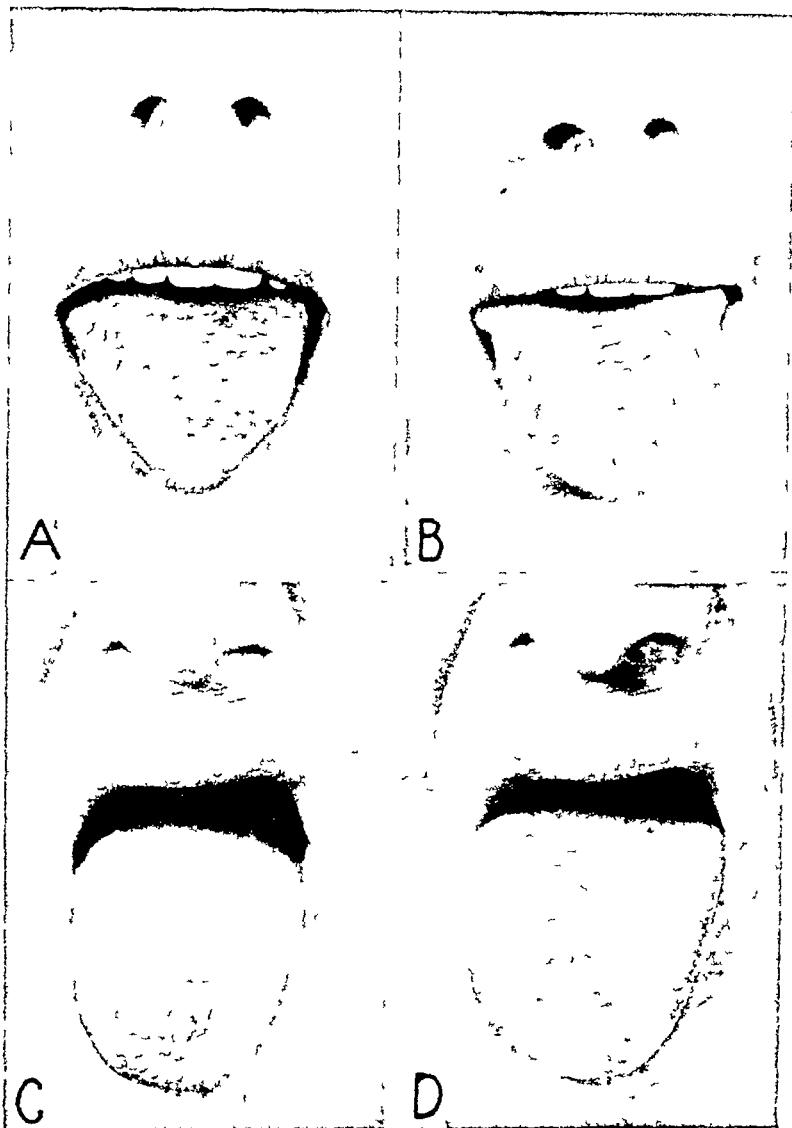

Fig 2—A V D C-33368 Beefy red smooth tongue occurring as a relapse during the third month of pteroylglutamic acid therapy. B Repeat photograph showing normal lingual mucosa twenty days after the injection of 0.050 mg of vitamin B<sub>12</sub>. C, M J 25597 Scarlet red smooth tongue occurring as a relapse during the third month of pteroylglutamic acid therapy. D, Repeat photograph twenty-one days later showing normal lingual mucosa after the injection of 0.025 mg of vitamin B<sub>12</sub>.

The lingual response was never entirely satisfactory. During the first week of pteroylglutamic therapy, the tongue became more normal in color and in areas of previous atrophy filiform papillae reappeared. The papillae remained stubby, however, and an area at the tip of her tongue remained persistently red.

Early in the third month of pteroylglutamic acid therapy she complained of soreness and redness of the tongue lasting two or three days. Two weeks later these symptoms became persistent and she felt generally worse. Examination showed a beefy red tongue with out coat, completely devoid of papillae except in one small patch near the tip (Fig 2, A). There was no evidence of neurologic relapse and the blood values remained normal. The pteroylglutamic acid therapy was discontinued and 0.050 mg of vitamin B<sub>12</sub> was given intramuscularly. The redness and soreness of the tongue subsided within a week. On a check up examination twenty days after the injection the tongue was pink in color, lightly coated, and covered with filiform papillae of normal height (Fig 2, B). The neurologic status showed no objective changes.

M. J., 25597. This 58 year old farmer's widow was admitted to Duke Hospital on April 14, 1948. Two years previously she had developed a periodically sore tongue, lost her desire to eat, and had begun to lose weight. Her hands and feet became numb. She was confined to bed for several weeks by extreme weakness, but improved after injections were given by her family physician. Some months later she began to have progressive difficulty in walking, with gross unsteadiness. Two months before her hospital admission she became rapidly worse and was confined to bed, unable to stand or walk. Her family physician gave her oral medications and injections for pellagra without benefit.

On examination the patient was a thin, weak, apathetic woman appearing chronically ill. The tongue was pale and completely devoid of papillae. She was able to sit up in bed without assistance but was too weak to get out of bed, stand, or walk. The superficial sensations were impaired below the elbows and knees. The sense of motion and position was poor in the lower extremities. The vibratory sense was impaired over the lower ribs and absent at the pelvis and below. The plantar reflexes were extensor.

On admission to the hospital the hemoglobin was 6.8 grams per 100 c.c., RBC, 1,750,000, WBC, 2,360, hematocrit 19.5 per cent, average cell volume, 112 cubic micra, and reticulocytes, 5.0 per cent. During the first ten days in the hospital an incomplete, apparently spontaneous remission in the anemia occurred. There was no improvement, however, in the appearance of the tongue. After ten days of observation, the administration of pteroylglutamic acid was begun in a dose of 50 mg per day by mouth. A secondary reticulocytosis occurred. One week after the start of pteroylglutamic acid therapy, beginning regeneration of lingual papillae was evident. After eighteen days of therapy the papillae were of normal height. By this time the patient had gained strength and was able to sit up three to four hours a day as well as walk about the ward holding to furniture. After four weeks of anti-anemic therapy the blood values were entirely normal. After six weeks the dose of pteroylglutamic acid was reduced to 30 mg daily and she returned home.

General improvement continued. On a check up examination two months after the beginning of pteroylglutamic acid therapy, however, the tongue was observed to be reddened at the tip. The papillae remained tall. Five weeks later she complained of a sore, "scalded" tongue. Examination showed it to be scarlet red in color and entirely smooth (Fig 2, C). Her dietary habits were reinvestigated and it appeared that her food had been well selected and above average in nutritional adequacy. The blood values remained normal and neurologic examination showed continued improvement, certainly no relapse.

At this time the pteroylglutamic acid administration was stopped and 0.025 mg of vitamin B<sub>12</sub> was injected intramuscularly. The lingual soreness promptly subsided and after one week the color of the tongue was grayish pink and the dorsum was covered with a uniform crop of budding filiform papillae (Fig 2, D). She believed that her strength and motor ability had improved.

The following patient was one of five showing the lingual manifestations of untreated pernicious anemia in whom the injection of vitamin B<sub>12</sub> in a dose of 0.001 mg daily to 0.010 mg in a single dose led to regeneration of lingual papillae in 5-7 days.

W S, C 6035 This 66 year old white man was admitted to Duke Hospital on Aug 24, 1948 For over three years he had had periodic redness and soreness of the tongue attributed by physicians to his habit of chewing "home cured" tobacco Five weeks before admission, his hands and arms became numb, weak, and clumsy so that he had to quit work and could scarcely dress himself or write

Fig 3—A W S C-6035 Dusky red tongue lacking papillae in a patient with untreated pernicious anemia B Repeat photograph five days after the injection of 0.010 mg of vitamin B<sub>12</sub> showing regeneration of papillae

On examination the tongue was deeply furrowed, completely lacking in coat, dusky red in color, and completely devoid of papillae (Fig 3, A) His grip was extremely weak Tendon reflexes in the upper extremities were absent The superficial sensations were blunted about the hands and forearms and the vibratory sense was impaired below the wrists and at the ankles The hemoglobin was 12.8 grams per 100 cc, RBC, 3,400,000, WBC, 6,800, hematocrit, 35 per cent, and average cell volume, 103 cubic micra Examination of the bone marrow showed early megaloblastic development

He was given 0.010 mg of vitamin B<sub>12</sub> intramuscularly Five days later the tongue was normal in color and its dorsum was covered with medium tall filiform papillae (Fig 3, B) in spite of his continuing to chew tobacco

#### DISCUSSION

Periodic atrophy and inflammation of the lingual mucosa, so vividly described nearly fifty years ago by Hunter<sup>15</sup> as often the first symptom of pernicious anemia, has become a well-recognized clinical manifestation of the disease Significant abnormalities of the lingual mucosa are seen, with or without hematologic or neurologic manifestations, in about one-third of present-day patients with pernicious anemia in relapse Mucosal changes of similar appearance may result, of course, from the lack of common vitamin B components in

the diet,<sup>16</sup> from iron deficiency<sup>6</sup> in association with serious hepatic disease or abdominal neoplasms, from use of oral penicillin,<sup>19</sup> etc

Among the benefits of a diet rich in liver in the treatment of pernicious anemia, Minot and Murphy<sup>15</sup> observed a gradual return of normal lingual mucosa in a matter of a few weeks or months. With potent liver extract or hog stomach therapy a more rapid lingual response occurs. Filiform papillae sprout from smooth tongues in five to seven days and attain a normal height in two to three weeks. Relapses do not occur with adequate maintenance therapy. The lingual abnormalities of pernicious anemia are not affected by nonspecific therapy, the administration of the common vitamin B components<sup>22</sup> etc. The lingual response may serve accordingly as a useful and reliable therapeutic test for pernicious anemia in patients who have little or no anemia or in whom the cause of lingual or neurologic disease is in doubt.

In the therapeutic evaluation of pteroylglutamic acid in pernicious anemia most attention has been given to the hematologic and neurologic aspects. A few investigators have noted poor lingual responses at the beginning of therapy and relapses later during maintenance.<sup>11, 12, 23</sup> The frequency of this occurrence is uncertain. It appears to be especially common in the patients reported who developed neurologic relapses. In our six patients whose lingual responses were poor or who later relapsed the blood levels remained below normal and neurologic disease progressed in one and the red cell count fell significantly in another. Had the pteroylglutamic acid therapy been continued longer in these patients a higher incidence of hematologic and neurologic failures might well have been observed.

The regeneration of lingual mucosa following the injection of vitamin B<sub>12</sub> after relapse has occurred during pteroylglutamic acid therapy shows that the former substance has a nutritional value lacking in the latter. The promptness of the response equal to that observed in patients with untreated pernicious anemia suggests that the pteroylglutamic acid failed to correct an existing deficiency rather than having exerted a positively harmful effect.<sup>7, 14, 1</sup> The effect of vitamin B<sub>12</sub> in correcting this type of lingual relapse appears to be equal to that expected from liver extract as preliminary reports indicate it to be in other respects.<sup>1, 23, 25, 2</sup>

Whether or not the different manifestations of pernicious anemia—arrest in hemopoiesis, atrophy and inflammation of the lingual mucosa, and disease of the peripheral and central nervous system—represent one or more closely related nutritional deficiencies has been a perennial question.<sup>1, 2, 21</sup> Each of these manifestations is dissociated from the others and may occur singly or in combination as the disease first appears or relapses. Potent liver extracts however refined or fractionated and hog stomach preparations affect all aspects of pernicious anemia in parallel. The impression has arisen that pteroylglutamic acid corrects one portion of the basic deficiency, having an entirely satisfactory hematologic effect but being entirely ineffective regarding the neurologic manifestations.<sup>14, 1, 24, 9</sup> The incomplete hematologic remissions,

the lingual relapses, and the occasional favorable neurologic results of pteroylglutamic therapy indicate that on the contrary the compound has an irregular effect on all manifestations of the disease rather than failing consistently in any one. The cause for individual variability in therapeutic response remains to be determined.

#### CONCLUSIONS

- 1 The lingual manifestations of pernicious anemia in relapse may respond well or poorly to synthetic pteroylglutamic acid.
- 2 Two patients taking 30 and 50 mg of pteroylglutamic acid daily developed in the third month of therapy acutely sore tongues with mucosal atrophy. The lingual abnormalities disappeared within five to seven days after the injection of vitamin B<sub>12</sub>.
- 3 The lingual mucosal atrophy of five patients with untreated pernicious anemia responded in five to seven days to injections of vitamin B<sub>12</sub>.
- 4 The therapeutic limitations of pteroylglutamic acid in pernicious anemia relate to all manifestations of the disease—anemic, neurologic, and lingual—rather than to merely the neurologic.

# CAPILLARY FRAGILITY STUDIES (GOTHLIN TEST) ON ONE HUNDRED PATIENTS RECEIVING DICUMAROL

RICHARD A. JUBELIRFR, M.D., AND HELEN I. GLUECK, M.D.  
CINCINNATI, OHIO

WHILE following the clinical course of a number of patients receiving Dicumarol therapy, hemorrhage occasionally has been found to occur without premonitory signs when the prothrombin concentration did not reach excessively low levels. Likewise it was frequently observed that the prothrombin concentration fell far below the so-called hemorrhagic levels without the development of hemorrhage. It was decided, therefore, to study a large group of patients receiving Dicumarol for varying intervals of time in order to ascertain if any correlation existed between the occurrence of hemorrhage and increased capillary fragility.

## METHOD

The modified Gothlin test<sup>1, 2</sup> was selected because of the ease of its performance, and because it has been used increasingly in many studies during the last few years in this country. Because the test has been subject to various modifications since Gothlin's original work, the method used in the present studies will be briefly outlined.

(1) Two areas, 6 cm. in diameter, were marked off in each antecubital area, noting blemishes and marks which might later be confused with petechiae. (2) A standard blood pressure cuff was applied on each arm for fifteen minutes and maintained at 35 mm. of pressure. The cuff was then released and all petechiae in each area were noted, using a good light and a magnifying lens of 5 diopters. (3) The second stage was then repeated one hour after the first, using the same procedure as previously described but maintaining the pressure at 50 mm. for fifteen minutes. (4) The petechial index was calculated as follows: To the number of petechiae in both arms occurring at 35 mm. multiplied by 2 were added the additional number of new petechiae occurring at 50 millimeters. The final index represented the sum of these two figures. Eight or less was considered normal, 9 to 12 borderline, and 12 or over increased.

Since repetition of the test before three weeks may produce false positive readings,<sup>1</sup> most patients were tested about the third week after the onset of their illness when they had received a fairly large quantity of Dicumarol.

Quick's method of determining the prothrombin time was used throughout the study. In this hospital the prothrombin level is always reported not only as prothrombin time in seconds but also as per cent of normal concentration. In our laboratory 12 to 14 seconds is the usual range of 100 per cent undiluted plasma, 16 to 19 seconds represents 50 per cent plasma, 22 to 26 seconds, 25 per cent plasma, and 40 to 47 seconds 10 per cent plasma concentrations.

### RESULTS

The data on ninety four consecutive patients receiving Dicumarol are summarized in Table I. Of these seventy five were being treated for acute myocardial infarction, fifteen for thrombophlebitis, three for rheumatic heart disease with embolic complications, and one for a surgical procedure.

# CAPILLARY FRAGILITY STUDIES (GOTHLIN TEST) ON ONE HUNDRED PATIENTS RECEIVING DICUMAROL

RICHARD A. JUBELIRER, M.D., AND HELEN I. GLUECK, M.D.  
CINCINNATI, OHIO

WHILE following the clinical course of a number of patients receiving Dicumarol therapy, hemorrhage occasionally has been found to occur without premontory signs when the prothrombin concentration did not reach excessively low levels. Likewise it was frequently observed that the prothrombin concentration fell far below the so-called hemorrhagic levels without the development of hemorrhage. It was decided, therefore, to study a large group of patients receiving Dicumarol for varying intervals of time in order to ascertain if any correlation existed between the occurrence of hemorrhage and increased capillary fragility.

## METHOD

The modified Gothlin test<sup>1, 2</sup> was selected because of the ease of its performance, and because it has been used increasingly in many studies during the last few years in this country. Because the test has been subject to various modifications since Gothlin's original work, the method used in the present studies will be briefly outlined.

(1) Two areas, 6 cm. in diameter, were marked off in each antecubital area, noting blemishes and marks which might later be confused with petechiae. (2) A standard blood pressure cuff was applied on each arm for fifteen minutes and maintained at 35 mm. of pressure. The cuff was then released and all petechiae in each area were noted, using a good light and a magnifying lens of 5 diopters. (3) The second stage was then repeated one hour after the first, using the same procedure as previously described but maintaining the pressure at 50 mm. for fifteen minutes. (4) The petechial index was calculated as follows: To the number of petechiae in both arms occurring at 35 mm. multiplied by 2 were added the additional number of new petechiae occurring at 50 millimeters. The final index represented the sum of these two figures. Eight or less was considered normal, 9 to 12 borderline, and 12 or over increased.

Since repetition of the test before three weeks may produce false positive readings,<sup>1</sup> most patients were tested about the third week after the onset of their illness when they had received a fairly large quantity of Dicumarol.

of hemorrhage with Dicumarol, and finally some of the pathologic findings which have been observed with large doses of Dicumarol

Little data exist comparing the various methods of detection of increased capillary fragility Bell, Munio, Lazarius, and Scarborough<sup>8</sup> compared the positive pressure Gothlin test method with a negative pressure method in a group of 142 normal students They found that each test was consistent in itself, but that no correlation existed when positive pressure methods were compared with negative pressure methods They could not conclude which test was the most satisfactory for detecting increased capillary fragility In a later paper,<sup>9</sup> while studying the effects of vitamin P and C, they gave a very complete and careful analysis of all the methods of studying increased capillary fragility They observed that even in patients with frank scurvy, the capillary fragility test was negative in about one-third of their cases with the Gothlin test, and an even smaller percentage of positive reactions was found with the negative suction method Greene<sup>10</sup> reported that 92 per cent of well-nourished children receiving supplementary vitamin C in their diets still showed a positive Gothlin test, whereas only 12.5 per cent of malnourished children with a low vitamin C intake gave a positive test He concluded that the test was not specific for the diagnosis of scurvy Beaser and co-workers<sup>11</sup> noted that with negative pressure methods contiguous areas in the same arm showed marked fluctuation in the number of petechiae from site to site Moreover, many patients had fewer petechiae at higher negative pressures than at lower pressures They therefore selected the Wright-Lilienfeld<sup>4</sup> positive pressure method for studying these cases Both diabetic and hypertensive patients showed an increased tendency to capillary fragility, the highest incidence (100 per cent) occurring when both diseases were present A considerable portion of the control group gave a positive index Increasing age seemed to play some role in the results Griffith and Lindauer<sup>12</sup> noted an increased incidence of apoplexy and retinal hemorrhage in 265 hypertensive patients studied with the Gothlin test In a larger series of 1,200 hypertensive subjects subsequently reported,<sup>13</sup> it was found that 20 per cent showed increased capillary fragility This tendency seemed to be modified by the use of rutin

Schweppe and co-workers<sup>14</sup> have compared three methods of measuring increased capillary fragility The suction or negative pressure test, the Gothlin test, and a cuff test with the manometer raised rapidly to 300 mm. of mercury Of forty-four hypertensive patients examined, 16 per cent showed a tendency to increased capillary fragility when measured by the Gothlin test and the negative pressure test, while at the same time 25 per cent showed a positive cuff test Thirteen per cent of thiocyanate-treated patients showed marked increased fragility However, as the cardiac status of the patients improved, the test often became negative even though the drug was continued Twenty per cent of the control group showed some abnormality They emphasized that no general conclusions regarding the entire capillary bed could be deducted from the reaction of the cutaneous capillaries Patients with advanced nephritis, vascular bleeding, retinitis, and ecchymoses were often encountered without the develop-

ment of a positive Gothlin test. In contrast to the findings of Schweppe<sup>14</sup> Shanno<sup>1</sup> and Griffith<sup>12</sup> have emphasized that thiocyanate therapy may predispose to the development of petechiae.

Wolffe and Danish<sup>16</sup> reported two cases of subconjunctival hemorrhage in which the Gothlin test was normal. Taylor and Page<sup>17</sup> while studying the clinical effects of rutin, using the Rumpel Leede test, noted marked variations from month to month in their control group of hypertensive patients. The test occasionally was positive in patients without cardiovascular disease. Older, acutely ill patients seemed much more susceptible to increased capillary fragility. Whereas a significant degree of arteriosclerosis gave a high incidence of positive tests, as the general status of the patient improved, particularly with improvement of congestive failure, the test often became negative. The phase of the menstrual cycle also may alter the test.<sup>18</sup>

Rodriguez and Root<sup>19</sup> noted a marked increase in positive Gothlin indices in patients with diabetic retinitis. This abnormality seemed more related to the duration of the diabetes than to the chronological age of the patient. The longer the diabetes had persisted the more likely was the capillary fragility increased. Wagener has made similar observations.<sup>20</sup> Finally, Peck and Copley<sup>21</sup> have discussed in detail physiologic factors which may influence capillary fragility and have emphasized that most cutaneous tests may not satisfactorily explain the true status of the capillary bed in more remote portions of the body.

The pathologic changes produced by Dicumarol toxicity are still not completely understood. Bingham, Meyer and Pohle<sup>2</sup> noted marked capillary dilatation in dogs receiving fatal doses of the drug. This capillary dilatation was widespread, involving not only capillaries but venules and arterioles. Frequently gross hemorrhage was noted in the gastrointestinal tract and pleural spaces. Interestingly enough the vascular walls appeared intact, hemorrhage occurring by diapedesis of red cells.

Similar findings of marked engorgement of the capillaries, venules and arterioles were found by Sheelin and Lederer<sup>3</sup> in a patient dying from uncontrolled hemorrhage after the administration of Dicumarol. Whereas hemorrhage was extremely widespread, no disassociation of the continuity of the vessel walls could be observed. They felt that the probable extravasation of blood was due to diapedesis of the red blood cells, rather than to rupture of the walls of the vessels.

In considering the patients who were on Dicumarol for long periods of time, it is particularly interesting to note Link's observation<sup>4</sup> that rabbits fed spoiled sweet clover repeatedly for seven years, resulting in a marked reduction of their prothrombin concentration for at least half of their life span, died of old age without apparent effect of the drug.

Although Barker and associates<sup>5</sup> have emphasized that hemorrhage is less likely to develop in patients receiving Dicumarol, if the prothrombin concentration is not lower than 10 per cent of normal, the literature contains many well documented cases of hemorrhage occurring when the prothrombin concentration was above the so called crucial level.<sup>3, 4</sup> Bruzelius<sup>22</sup> observed that in 28 per cent of patients with gross hemorrhage, there was no relationship between

the occurrence of hemorrhage and excessively low prothrombin concentration. It has likewise been observed by many that the prothrombin concentration of the blood often falls to levels of less than 5 per cent of normal without the development of hemorrhage.<sup>3, 24</sup> Overman and co workers<sup>27</sup> called attention to this in some of their earlier publications stating, "The fact that hemorrhage does not always accompany diastolic reductions in prothrombin concentration from a single large dose of Dicumarol, suggests that the onset of bleeding must represent more than a simple suppression of the normal prothrombin levels." Thorenson<sup>28</sup> observed hemorrhage in a patient given large doses of Dicumarol three and one-half months after the last dose of the drug. There was no correlation between the occurrence of hemorrhage and the level of prothrombin concentration. Bollman and Preston<sup>29</sup> noted that some other factor than the depression of prothrombin seemed necessary for the production of hemorrhage.

To detect and anticipate hemorrhage in patients receiving Dicumarol, careful observation of the patient and meticulous laboratory determinations must be carried out. Although, as previously emphasized, hemorrhage may occur at any level of prothrombin concentration, it is not a serious complication in careful hands. Thus, Allen<sup>30</sup> reported major hemorrhage in only 1.9 per cent of 1,686 patients receiving Dicumarol postoperatively. Barker<sup>25</sup> emphasized that definite bleeding is rare if the prothrombin concentration does not fall below 10 per cent of normal, and then it occurs in only 4 per cent of cases.

#### SUMMARY AND CONCLUSIONS

1 One hundred patients receiving Dicumarol were studied to determine if any correlation existed between the occurrence of hemorrhage and increased capillary fragility as measured by the Gothlin test.

2 Six of these patients had received Dicumarol continuously, the shortest period was three months and the longest, nineteen months. None of these patients demonstrated a positive Gothlin test.

3 Hemorrhage was observed seven times in 100 cases of patients receiving Dicumarol. In none of these was the Gothlin index positive.

4 Seven patients demonstrated a positive Gothlin test who gave no clinical evidence of hemorrhage.

5 The interpretation of the various tests for the detection of increased capillary fragility is briefly discussed.

6 The pathologic findings of hemorrhage occurring with Dicumarol are reviewed.

7 This study suggests that the status of the cutaneous capillaries as detected by the Gothlin test does not reflect alterations which may occur in other portions of the capillary bed.

8 Careful clinical observation and meticulous laboratory control are necessary to detect and prevent hemorrhage in patients receiving Dicumarol.

# THE USE OF RUSSELL VIPER VENOM AND LECITHIN AS THROMBOPLASTIN IN THE ESTIMATION OF PROTHROMBIN

C A MAWSON, M Sc, PH D  
READING, ENGLAND

WITH the increasing use of dicoumarin in anticoagulant therapy, methods for the estimation of prothrombin have become the subject of widespread controversy. Most published methods are based upon the one-stage procedure of Quick<sup>1</sup> in which dried rabbit brain is used as thromboplastin, but many workers have found the preparation of this reagent troublesome and have had difficulty in reproducing the reference curve whereby Quick calculates the prothrombin concentration from the clotting time. For this reason rabbit brain extract has often been replaced by Russell viper venom (Fullerton<sup>2</sup>) which is packed in a convenient form (Stypven, Burroughs Wellcome) and remains stable for long periods as a dry powder. Addition of lecithin (Hobson and Witts<sup>3</sup>) to venom gives a preparation much more active than Quick's brain extract and which appears to have all the properties of a complete thromboplastin. However, when venom reagents are used for estimating prothrombin in plasma from patients receiving dicoumarin, the results obtained are usually much higher than those found by Quick's method (e.g., Wilson<sup>4</sup>) and these discrepancies have led Macfarlane<sup>5</sup> to condemn the use of venom as likely to give a false sense of security at a time when an estimation using brain thromboplastin would reveal a disastrously low concentration of prothrombin.

It is generally admitted that the most satisfactory method for prothrombin estimation is a two-stage procedure such as that first introduced by Warner, Brinkhous, and Smith<sup>6</sup> and it is very strange that among the many one-stage methods described in the literature the results obtained have seldom been directly compared with those of a two stage method. This is probably due to the fact that the method of Warner, Brinkhous, and Smith calls for purified reagents of standard activity which are difficult to prepare and somewhat unstable. These objections were largely overcome by Herbert,<sup>7</sup> a modification of whose method has been used in the present investigation, and it has been possible by the use of this method to compare estimations of prothrombin in dicoumarin plasma by the two-stage procedure with results given by several different one-stage methods.

## METHODS

*Blood Sampling*—Decalcification was carried out by mixing 8 to 12 ml blood with 0.1 ml 10 per cent potassium oxalate, after which the blood was briefly centrifuged so that some platelets remained in suspension. The presence of platelets assists in detection of the clot in the venom lecithin method.

### (1) *Venom Lecithin Method*—

*Lecithin*—A 10 per cent solution of crude Ovocleithin B P in alcohol was kept in the refrigerator.

From the Pathological Laboratory Royal Berkshire Hospital  
Received for publication Nov 18 1948

*Venom* A solution of 0.1 mg Styppen in 21 ml. water was stable for about a week at -12 C

*Venom Lecithin Reagent* Venom solution (0.5 ml) was mixed with  $\frac{N}{200}$  NaOH (1.5 ml) and lecithin (0.1 ml), placed in ice water and used within one hour (The concentration of the NaOH was such as to give a final pH of 7.0 to 7.4)

*Calcium Chloride* A solution containing 9.8 Gm  $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$  was made up to 100 milliliters. Dilution of 0.3 ml of this stock solution to 10 ml gave the 0.15 per cent  $\text{CaCl}_2$  used for the estimation. It was kept in a water bath at 38 C. This concentration is lower than that advised by Quick, who used more oxalate for decalcification of the blood.

*Apparatus* Many of the difficulties encountered in the use of venom and lecithin have been due to uncertainty in detection of the formation of the clot coupled with the fact that the clotting times are so short (normal, 6 to 8 seconds) that small timing errors are of decisive importance. A brightly illuminated water bath is essential, in which the tube must be kept immersed from the moment of addition of the  $\text{CaCl}_2$ . The bath used in this work consisted of a small accumulator jar (17 by 9 by 9 cm) standing on a black and white titration tile and filled with water at 37 to 39 C to within 0.5 cm of the top. The bath was simultaneously kept warm and illuminated by an adjustable lamp placed about 5 cm from the left side of the jar, level with the surface of the water and with the beam directed downward at an angle of 45 degrees. Glare from the lamp was prevented by a small vizard fixed to the edge of the shade.

*Procedure* Plasma (0.1 ml) and venom lecithin (0.1 ml) were mixed in a thin walled test tube (75 by 8 mm). The tube was shaken gently in the water bath for about fifteen seconds. 0.1 ml 0.15 per cent  $\text{CaCl}_2$  measured in a wide bore straight blood counting pipette was blown sharply into the tube and timing started immediately. The tube was held over the junction between the black and white portions of the tile at an angle of 10 to 20 degrees to the horizontal. The base of the tube rested on the surface of the water and the upper end was in contact with the wall of the jar just below the point at which it was held. The tube was rolled to and fro between the finger and thumb about its longitudinal axis, care being taken to maintain it at a constant angle so that the contents of the tube were not shaken. The tube was watched carefully from above until clotting occurred. The end point was the sudden appearance of a scalloped edge which was followed by a solid clot. The scalloped edge was a very precise phenomenon which could be timed with great accuracy, and was best seen in plasma containing platelets.

The method of timing is of crucial importance. Mechanical aids such as stop watches have the defect that considerable reaction time delays are involved in their use. The writer has found that the best method is to count the seconds, which eliminates errors of this nature. With a little practice it is possible to count seconds by means of a mnemonic such as "Photograph one photograph two etc." with an accuracy of  $\pm 1$  second per minute.

*Reference Curve* The following dilutions of plasma were made with 0.85 per cent NaCl—75, 50, 25, 12.5 and 6.25 per cent. The clotting times were observed as described with the exception that the 12.5 and 6.25 per cent dilutions sometimes did not show a scalloped edge but only the sudden appearance of floccules of fibrin. The "prothrombin index" was calculated in each case as,

$$\frac{\text{Clotting time of undiluted normal plasma}}{\text{Clotting time of diluted plasma}} \times 100$$

The mean indices from ten normal specimens of plasma are shown plotted against the plasma percentage in Fig. 1. The use of the prothrombin index rather than the clotting time made it easier to read results from the curve and also avoided difficulties due to variations in the clotting time of normal plasma with different batches of venom. Although any given batch gave very consistent results, it was advisable to check the clotting time

Fig 1—Variation of prothrombin index with saline dilution of normal plasma—mean of ten experiments

$$\text{Prothrombin index} = \frac{\text{Clotting time of normal plasma}}{\text{Clotting time of diluted plasma}} \times 100$$

at least one specimen of normal plasma each time a prothrombin estimation was done. The reference curves given by different batches of venom were practically identical when the prothrombin index was plotted against the dilution.

Reasons for preferring saline to prothrombin free plasma for dilution will be discussed later.

## (2) Brain Method—

**Brain Thromboplastin** Rabbit brain was dried by the method of Quick,<sup>8</sup> finely ground, and kept in screw capped vials filled with CO<sub>2</sub> at -12° C, under which conditions it is stable for many months (Owren<sup>9</sup>). Fifty milligrams dried brain were shaken with 1.25 ml 0.85 per cent NaCl and heated at 50° C for twenty minutes. The suspension was kept at 38° and measured with a wide bore 0.1 ml pipette. Using the technique described under (1) normal plasma gives prothrombin times of 12 to 13 seconds as stated by Quick,<sup>1</sup> though the reference curve prepared by dilution with 0.85 per cent NaCl (Fig 1) differs somewhat from that calculated from Quick's published data.

*(3) Lung Method—*

An extract of ox lung was made by the method of Smith, Warner, and Brinkhous<sup>10</sup> It was heated at 50 °C for twenty minutes and kept under CO<sub>2</sub> at -12 °C It was as stable as the dried brain, giving clotting times with normal plasma of 17 to 19 seconds when used in place of venom lecithin The reference curve for this material shown in Fig 1 was prepared as before by dilution of normal plasma with 0.85 per cent NaCl

*(4) Two Stage Method—*

*Stock CaCl<sub>2</sub>*, 9.8 Gm CaCl<sub>2</sub>, 6H<sub>2</sub>O made to 100 milliliters

*Saline CaCl<sub>2</sub>*, 1 ml stock CaCl<sub>2</sub> made to 100 ml with 0.85 per cent NaCl

*CaCl<sub>2</sub>, Thromboplastin* 1.25 ml brain thromboplastin prepared as in (2) was diluted to 20 ml with saline CaCl<sub>2</sub> The suspended particles of brain were not removed as their presence was important in detection of the clot The mixed reagent was stable for at least a week at -12 °C

*Barbitone Buffer* A solution of 0.5 gm sodium barbitone in 100 ml water was diluted with 350 ml 0.85 per cent NaCl and 11 ml N/1 HCl were added The pH was adjusted to 7.3 and the solution diluted to 500 ml with 0.85 per cent NaCl

*Fibrinogen* 30 ml unhemolyzed diluted plasma were mixed with 6 ml 30 per cent suspension of BaSO<sub>4</sub>, warmed to 38 °C and incubated for five minutes The mixture was shaken and incubated again for five minutes After centrifugation the supernatant was cooled in ice and 12 volumes of ice cold saturated NaCl were added slowly, with constant mixing After standing in ice for thirty minutes the fibrinogen was centrifuged down, drained, and dissolved in 10 ml 0.1 per cent potassium oxalate The solution was dialysed overnight at 4 °C against 300 ml 0.85 per cent NaCl containing 3 ml 5 per cent potassium oxalate and then frozen at -12 °C, under which conditions it was stable for about ten days Before use, the solution was thawed slowly and centrifuged while a little ice remained in order to remove profibrin (Owren<sup>9</sup>)

*Procedure* Two dilutions of plasma (1:125 and 1:25) were made with 0.85 per cent NaCl, and 0.5 ml of each was placed in a test tube To each tube was added 0.5 ml barbitone buffer and 10 ml CaCl<sub>2</sub> thromboplastin a stop watch being started at the moment of addition of the thromboplastin After about forty five seconds 0.2 ml of the first (1:50) conversion mixture was transferred to a thin walled clotting tube of the type used in the one stage method The cold fibrinogen solution (0.1 ml) was blown sharply into the clotting tube, which was held in the illuminated water bath, and a note was made of the conversion time used The counting of seconds was started at the moment of introduction of the fibrinogen and the tube was rotated and observed as in the one stage methods The clotting time was recorded and the procedure immediately repeated with a second sample from the same conversion mixture Successive samples were taken in this way until a clot formed in the conversion mixture which was the signal to proceed to the second conversion tube With normal plasma the minimum clotting time was 10 to 12 seconds with the 1:50 dilution and 14 to 18 seconds with 1:100 dilution, while the corresponding conversion times were about 1 and 2 minutes With plasma having a low prothrombin content the conversion times as well as the clotting times were considerably prolonged, but it was most unusual to encounter a conversion time for the 1:100 dilution longer than 15 minutes, with a clotting time of about 2 minutes Hence a complete estimation could usually be completed within twenty minutes

*Calculation* The prothrombin content of the test sample, expressed as a percentage of normal, was given by

$$\% \text{ Prothrombin} = \frac{\text{Clotting time with normal plasma}}{\text{Clotting time with test plasma}} \times 100$$

If the results of the 1:50 and 1:100 dilutions did not agree within 10 per cent, the experiment was repeated using intermediate conversion times It was advisable to determine the clotting times with dilutions of normal plasma each time an estimation was done so that deterioration of reagents might be detected

*Remarks* The modified two stage method just described differs in some respects from that of Herbert.<sup>7</sup> Barbitone buffer is used instead of glycylglycine and this is probably why maximum conversion occurs before instead of after clot formation. Rieben,<sup>11</sup> who also uses barbitone in a somewhat similar modification, has noticed the same difference.

Herbert's method for detection of the fibrin clot is technically difficult, but when thromboplastin containing particulate matter is used in an illuminated water bath clotting is easily detected. The fibrinogen in the conversion mixture seems gradually to accumulate on the particles of brain which move freely in the liquid as the tube is rotated. Suddenly the particles are held in a web of fibrin and the surface ceases to remain horizontal as the tube is turned, and this is the end point.

Herbert used dilutions of 1 100, 1 200, 1 400, and 1 800 in the conversion mixtures. A 1 50 dilution has been added here because plasma low in prothrombin gives inconveniently long conversion and clotting times at dilutions greater than 1 100. Results calculated from the mean of 1 50 and 1 100 dilutions were not significantly different from those obtained by the addition of 1 200, 1 400, and 1 800 dilutions.

## RESULTS

*Comparison Between Venom-Lecithin and Tissue Thromboplastins*—When comparisons were made between results of estimation of prothrombin by the venom-lecithin, brain, and lung thromboplastins it soon became evident that gross discrepancies were the rule rather than the exception. Systematic studies of patients receiving dicoumarin (Fig 2 and Table I) gave such alarming results that it was decided to follow all such cases in future by means of the two-stage procedure as well as by all three one-stage methods.

*Comparison Between One-Stage and Two-Stage Methods*—Owen and Bollman<sup>12</sup> have recently reported that when dicoumarin is given to dogs the fall in prothrombin as measured by the two-stage method is much less rapid and profound than would appear from results obtained by Quick's one-stage technique. Six\* patients receiving dicoumarin have been studied throughout the course of

\*Now twenty-three patients—at time of proofreading February 1949

Fig 2—Prothrombin in plasma of patient treated with dicoumarin Results by one stage method using

- 1 Venom lecithin
- 2 Brain
- 3 Lung

as thromboplastin.

treatment, and it has been found in each instance that the results were similar to those observed by Owen and Bollman in the dog. One of these cases is illustrated in Fig 3 from which the results obtained with lung thromboplastin have been omitted for the sake of clarity. The one stage results obtained by the brain method were nearly always lower than those found with the two stage technique, and all the curves showed that there was reasonably good agreement between the two stage method and the one stage venom lecithin method. When ox lung was used as thromboplastin in the one stage method the results were usually much lower than those found with rabbit brain. This is illustrated in Table I in which are included results from the above mentioned six patients, together with others from patients whose prothrombin was not estimated by all four methods throughout the course of dicoumarin therapy.

**Effect of Mixing Plasmas**—When normal plasma was mixed with dicoumarin plasma the discrepancy between the prothrombin concentration as estimated by the venom lecithin and brain thromboplastins was considerably reduced. When venom lecithin was used a mixture of normal and dicoumarin plasma gave a clotting time which differed little from the “expected” clotting time calculated from the percentage prothrombin found in the dicoumarin plasma by the venom lecithin method (Table II). However, with brain

Fig 3—Prothrombin in plasma of patient treated with dicoumarin  
 One-stage method full line = venom-lecithin broken line with crosses = brain  
 Two-stage method dotted line with circles

thromboplastin, this table shows that in nearly every case the clotting time of the mixture was *less* than the "expected" clotting time calculated from the percentage prothrombin found in the dicoumarin plasma by the brain method. Similar results have been reported by Owen and Bollman,<sup>12</sup> using mixtures of normal and dicoumarin dog plasma, when prothrombin was estimated by the brain one-stage method. If the calculation of the expected clotting time is valid, the addition of normal plasma caused a shortening of the clotting time greater than could be accounted for by the added prothrombin as estimated by the brain method, whereas no such potentiating effect was observed when venom-lecithin was used.

*Influence of Factor 5*—Owen and Bollman<sup>12</sup> have suggested that the discrepancy between the results of the one-stage and two-stage methods is due to the slow conversion of prothrombin to thrombin in dicoumarin plasma, and believe that this is due to a deficiency of Factor 5 (Owren<sup>9</sup>) which is identical with Quick's<sup>13</sup> labile factor. Factor 5 is rapidly reduced when plasma is stored (Quick<sup>14</sup>) and its oxidation is revealed by an increase in the "prothrombin time" which occurs in spite of the fact that the prothrombin content of stored plasma remains constant for about three weeks (Ware, Guest, and Seegers<sup>15</sup>). If the discrepancy between the venom-lecithin and brain one-stage methods was due to a deficiency of Factor 5 in dicoumarin plasma, a similar discrepancy

*Example of calculation of expected clotting time in an experiment using venom lecithin*

Clotting time of normal plasma 7½ seconds

Clotting time of dicoumarin plasma 15½ seconds

Prothrombin index of dicoumarin plasma =  $\frac{7.5}{15.5} \times 100 = 48$

Percentage prothrombin in dicoumarin plasma (from Fig 1) = 5 per cent.

Mixture of 1 part normal + 3 parts dicoumarin plasma should give  $\frac{100 + 7.5}{4} = 44$  per cent prothrombin

From Fig 1 a plasma containing 44 per cent prothrombin should have an index of 68

The clotting time of a plasma having an index of 68 would be  $\frac{7.5}{68} \times 100 = 11$  seconds

Hence the expected clotting time of the mixture is 11 seconds

should exist when stored plasma is tested by the same methods. However, the "prothrombin percentage" found by the venom lecithin one stage method with stored human plasma is nearly always *lower*, not higher, than the result obtained with rabbit brain. A few experiments in which dicoumarin plasma has been mixed with prothrombin free normal plasma containing Factor 5 (human plasma treated with  $\text{BaSO}_4$  and ox plasma passed through a Seitz filter) have given no evidence that dicoumarin plasma is deficient in this factor. Dicoumarin plasma will itself reduce the clotting time of stored human plasma in spite of its low prothrombin content, but results from such mixtures are difficult to interpret since each of these plasmas contains factors deficient in the other.

*Influence of Venom Lecithin on Thrombin*—The possibility existed that the short clotting times obtained with venom lecithin were due to acceleration

of the activity of thrombin. This was investigated by observing the effect of adding venom-lecithin, brain, or saline to calcium chloride and thrombin and then adding fibrinogen. The fibrinogen was prepared by adsorption of human plasma with  $\text{Ca}_3(\text{PO}_4)_2$ , precipitation with ether (Kekwick and co-workers<sup>16</sup>), reprecipitation with 1.2 volumes of saturated NaCl, and removal of profibrin by freezing. It contained 69 per cent of clottable protein. It was found (Table III) that venom-lecithin, brain, and also venom-lecithin plus brain all had a slightly inhibitory action on the activity of thrombin.

TABLE III INFLUENCE OF THROMBOPLASTINS ON THROMBIN ACTIVITY  
(Each Tube Contained 0.1 Ml. 0.15 Per Cent CaCl<sub>2</sub> and Timing Was Started After Addition of 0.1 Ml. Fibrinogen to the Mixture)

	ML. SOLUTIONS ADDED			CLOTTING TIME
	THROMBOPLASTIN	THROMBIN	SALINE	
Experiment 1	Venom lecithin 0.1	0.0	0.1	No clot 30 min

	Venom lecithin 0.1 plus brain 0.1	0.1	0.0	22½ sec

Experiment 1—Thrombin 0.2 mg. per milliliter fibrinogen 0.15 per cent

Experiment 2—Thrombin 0.4 mg. per milliliter fibrinogen 0.30 per cent

The thrombin used was Parke Davis Thrombin Topical

*Prothrombin Conversion Time With Different Thromboplastins*—It has been pointed out by Warner, Binkhous, and Smith<sup>6</sup> that the prothrombin conversion time of plasma varies with the prothrombin content, and this is illustrated by the data shown in Fig. 4, all of which are taken from the records of one patient who was treated with dicoumarin for a month. These results were obtained using the modified Herbert technique with brain thromboplastin, and it seemed possible that the discrepancy found in the one-stage experiments between venom-lecithin and brain might be due to the former thromboplastin giving very much more rapid conversion of prothrombin to thrombin than the latter. Experiments were therefore done in which thromboplastins other than brain were used in the two-stage method. Table IV shows that with normal plasma, brain gave the shortest conversion times and lung the longest, with venom-lecithin occupying an intermediate position. It is also evident that at the lower dilutions the three thromboplastins produced the same amount of thrombin, so the influence of antithrombin may be discounted. The lengthened clotting times obtained with venom-lecithin at the higher dilutions were probably due to the comparative instability of this reagent. If the antithrombin effect had been of any importance it should have been

Fig 4—Variation of prothrombin conversion time with prothrombin concentration in a patient treated with dicoumarin  
Conversion mixtures dots = 1:0 crosses = 1:100

seen in the 1:50 dilution, but here a  $\frac{3}{4}$  minute conversion with brain gave the same thrombin clotting time as resulted from a  $2\frac{1}{2}$  minute conversion with lung

The experiments reported in Table IV were all done with 1:16 dilutions of the three standard one stage thromboplastins and the possibility remained that different results might be obtained at higher concentrations of thromboplastins especially if normal and dicoumarin plasma were compared. This was proved not to be the case by comparing conversion times using dilutions between 1:5 and 1:20 (Table V). With both normal and dicoumarin plasma the conversion time with venom lecithin was greater than it was with brain at all concentrations of thromboplastin tested.

TABLE IV RESULTS OF TWO STAGE TEST USING NORMAL PLASMA WITH VARIOUS THROMBOPLASTINS

The usual dilution of thromboplastin for the two stage method is 1/16

#### DISCUSSION

*Use of Isotonic Saline for Dilution of Plasma*—It has been shown in Fig 4 that low concentrations of prothrombin are associated with prolonged conversion times, and for this reason normal saline has been used for dilution of plasma in the preparation of standard reference curves. If prothrombin free plasma is used as advocated by many workers, conditions of rapid conversion are imposed upon mixtures of low prothrombin content which would not exist in undiluted plasma of similar prothrombin content. Table VI shows that when prothrombin is removed from plasma by adsorption with barium sulfate and the prothrombin free plasma is used as a diluent for the plasma from which it was prepared, the conversion time of the diluted plasma differs very little from that of the undiluted plasma. When plasma is diluted with saline, however, the conversion time is roughly doubled when the concentration is halved. This can be seen both in Table VI and Fig 4, and is confirmed each time a two stage estimation is performed. Inspection of Fig 4 will show that when prothrombin is reduced by dosage with dicoumarin the conversion time behaves as it does when plasma is diluted with saline, and not as it does when the dilution is made with prothrombin free plasma.

TABLE VI EFFECT OF PROTHROMBIN FREE PLASMA ON CONVERSION TIME OF NORMAL AND DICOUMARIN PLASMA (CONVERSION TIME IN SECONDS)

NATURE OF PLASMA	1/50 CONVERSION MIXTURE	1/100 CONVERSION MIXTURE
Normal	84	178
1 part normal + 3 parts prothrombin free normal	95	240
Infective hepatitis	64	101
1 part infective hepatitis + 3 parts prothrombin free infective hepatitis	95	188
Normal	125	235
Equal parts normal and prothrombin free normal	135	215
Dicoumarin	331	614
Equal parts dicoumarin and prothrombin free dicoumarin	240	500

The prothrombin free plasmas were prepared by adsorption with barium sulfate and contained no prothrombin detectable by either venom lecithin or brain one stage methods. The dicoumarin plasma had been kept at -1°C for two days.

The results obtained with dicoumarin plasma (Table VI) are interesting because this plasma had been kept at  $-12^{\circ}\text{C}$  for two days and had lost a considerable proportion of its original content of Factor 5. This is shown by the fact that the conversion times were 149 and 253 seconds for the 1:50 and 1:100 conversion mixtures when the plasma was fresh, whereas the 2-day-old plasma gave the conversion times shown in the table of 240 and 500 seconds respectively. In spite of this loss of Factor 5 (which is recognised as a substance essential for rapid conversion of prothrombin to thrombin) when the plasma was diluted to 50 per cent with prothrombin-free plasma the conversion times were rather less than those of the undiluted plasma. Since one-stage methods measure the rate of formation of thrombin and clotting may occur in normal plasma when about 5 per cent of the prothrombin has been converted to thrombin,<sup>5</sup> it is obvious that if conversion could be made instantaneous a plasma containing only 5 per cent of the normal prothrombin might give the same clotting time as a normal plasma tested in the usual way. An approach to this situation was reported by Honorato<sup>17</sup> who found that when human plasma was diluted with concentrated prothrombin-free dog plasma the "prothrombin time" remained at 11 to 13 seconds until the mixture contained less than 10 per cent of normal plasma.

Another reason for not using prothrombin-free plasma for dilution is the fact that its properties depend so much upon the method adopted for removal of prothrombin. This has been shown by Conley and Morse<sup>18</sup> and by the writer (unpublished data) who has found that if prothrombin-free plasma is prepared by adsorption with  $\text{BaSO}_4$ ,  $\text{Ca}_3(\text{PO}_4)_2$  or  $\text{Al}(\text{OH})_3$ , or by Seitz filtration, and is used for diluting normal plasma in the construction of reference curves of the type shown in Fig. 1, four different curves are obtained, each of which differs from the saline-dilution curve. Consequently, if the prothrombin index of an unknown plasma is referred to these curves five different results will be obtained for each of the thromboplastins, all of which will be lower than the two-stage result except when the index obtained with venom-lecithin is referred to a saline-dilution curve. Since there does not seem to be any satisfactory reason for preferring one form of prothrombin-free plasma to another, and since dilution with saline can give results which correspond with those of the two-stage method, dilution with saline has been used throughout this work.

*Discrepancy Between Results With Venom-Lecithin and Brain*—The reason for the failure of the various one-stage methods for prothrombin estimation to give concordant results when used with dicoumarin plasma has not been found, but certain possibilities have been eliminated. The short clotting times obtained with venom-lecithin are not due to activation of thrombin (Table III) or to acceleration of prothrombin conversion (Tables IV and V). The latter experiments are, however, only concerned with the completed conversion of prothrombin to thrombin, but it may be that with venom-lecithin the initial rate of thrombin formation is greater than it is with brain. This

is very likely, because the prothrombin time of normal plasma with venom lecithin is only half of that observed with brain and one third of that obtained with lung thromboplastin

To explain the discrepancies observed in results with dicoumarin plasma on the basis of initial conversion rates it would seem to be necessary to show that with venom lecithin the conversion rate of dicoumarin plasma is initially more nearly equal to that of normal plasma than it is when brain is used as thromboplastin. The results given in Table II are insufficient to decide this point. They show that a mixture of normal with dicoumarin plasma has a greater effect on the results with brain thromboplastin than with venom lecithin, and the only conclusion that can be drawn is that the coagulation defect of dicoumarin plasma revealed by the brain one stage method is not merely due to a deficiency of prothrombin. Assuming that the two stage method gives an accurate estimate of the prothrombin concentration, the venom lecithin one stage method described gives a closer approximation to the true prothrombin content than the rabbit brain method.

The important question remains—is the venom lecithin method suitable for control of dicoumarin therapy? The moment of clotting is more easily detected with the tissue thromboplastins and serious errors are inevitable with the venom reagent if the greatest care is not exercised. The fact that the venom reagent gives results more nearly equal to those of the two stage method than the tissue thromboplastins may be due to a happy chance but from the clinical point of view it is more desirable to estimate the tendency to bleed than to determine accurately the concentration of prothrombin in the plasma. Experience alone can show what is the danger point for any given method, and it is most unwise to apply criteria applicable to one method to results obtained with another. We believe that the important point is not the method used but the criteria employed for the interpretation of the result.

Our limited experience suggests that hemorrhage is unlikely if the plasma prothrombin as estimated by the venom lecithin or two stage methods is kept above 30 per cent of the normal value. In one instance a patient bled from a small ulcer in the mouth when the prothrombin by venom lecithin and two stage methods was about 60 per cent but in this case the result by Quick's method was 34 per cent. The latter figure is well above the accepted danger level for the brain method, which shows that caution must be observed whatever the "prothrombin time" may be. This is the only hemorrhagic incident which we have observed among eighteen patients controlled by means of the venom lecithin method and it was not sufficiently serious for the patient to notify her doctor until the bleeding had ceased. One other patient had a small hematoma of doubtful origin on her eyelid at the same time as a needle hematoma. Our clinical colleagues believe that satisfactory results can be obtained with a prothrombin concentration of 40 to 50 per cent as estimated by the two stage and venom lecithin one stage methods so we have had no opportunity of studying cases where the prothrombin had been reduced to

hemorrhagic levels. However, the tendency to bleed is sometimes not closely correlated with the prothrombin concentration and we must understand more about other clotting factors before we can control anticoagulant therapy with complete confidence.

#### SUMMARY

1 Modified methods and apparatus are described for the estimation of prothrombin by the one-stage and two-stage procedures.

2 When plasma from patients treated with dicoumarin was used, the two-stage method gave results in fair agreement with those obtained by a one stage method in which Russell viper venom and lecithin was used as the thromboplastin. When rabbit brain or ox lung was used, the prothrombin concentration found was lower than that given by the two-stage method.

3 Possible reasons for the discrepancies are discussed together with the significance of these observations in the control of anticoagulant therapy.

My grateful thanks are due to Dr R G Macfarlane and Dr R Biggs for opportunities for discussion of this work.

tion The degree of reduced prothrombin activity must be of such magnitude that it will prolong the whole blood clotting time, hence, it must be less than 40 per cent of normal activity before the titration is increased Based on experience with the normal dog given Dicumarol, the protamine titration does not increase until the prothrombin activity is less than 25 per cent of normal It may be that some revision of these data will be required in cases of reduced prothrombin activity in the presence of liver disease, as this aspect of the problem has not been investigated Normal or near normal prothrombin activity has been interpreted to indicate lack of any marked disturbance of the accelerator factor (accelerator globulin, prothrombin A, factor V)

*Heparinization* The therapeutic intravenous heparinization (35 to 50 mg per single total dose) markedly increases the clotting time but at these levels does not appreciably affect the protamine titration in otherwise normal blood If, however, the protamine titration scale is made more sensitive, the effect of heparin therapy can be detected readily Moreover, the patient with prothrombin deficiency given heparin may show an increased titration when neither the prothrombin deficiency nor the heparin alone is capable of increasing the protamine titration

*Hemophilia* Since in this disease the clotting time is prolonged, the protamine titration also may be increased This is probably a function of thrombin formation Not all hemophilic persons show an increased protamine titration, but in severe exacerbation the titration is generally increased

*Fibrin* Fibrin is the end point read in the protamine titration, consequently, in the absence of fibrinogen, no end point can be read

*Thrombocytopenia* The titration in our experience has been more frequently normal than abnormal in idiopathic thrombocytopenia However, patients with thrombocytopenia and increased protamine titration have been clinically improved and then titration returned to normal without evidence of any increase in the platelet count<sup>2</sup>

The magnitude of the changes produced in the protamine titration by the factors listed has been minimized by (1) the range of protamine used (increase of 0.02 mg per tube), (2) brisk shaking of tubes to initiate clotting, and (3) reading the titration no sooner than one hour after mixing heparinized samples in protamine tubes

#### SUMMARY

A method for measuring a clotting defect found in certain hemorrhagic states has been described

Two unexplained exceptions have been observed. These did not clot with 0.14 mg. protamine at the end of one hour but did clot into the normal range at the end of two hours. In a similar series of normal dogs the end point was found to be 0.12 mg. of protamine. Hereafter, the human normal end point is the one described. In women this end point may be increased during the menstrual period. Normally the clot appears firm and retracts in all tubes containing 0.14 mg. of protamine or more and is entirely fluid in all the tubes containing 0.12 mg. or less after one hour. Clot retraction, however, is slightly impaired in the tubes of high protamine concentration. The effect of other mild to moderate blood deficiencies on reading the end point is minimized by reading at one hour. This is especially true of thrombocytopenia and prothrombin deficiency. ✓

### 3 Sources of Error

- (a) Moist or unclean glassware or needles
- (b) Inaccurate measurement of protamine and/or heparin solutions
- (c) Poor venipuncture technique. In all coagulation studies it is imperative that the blood flow is prompt and free.
- (d) Failure to age protamine solution for twenty-four hours before use. Using protamine solution that has been standing for longer than one week or that has not been kept refrigerated. The antiheparin activity can be checked by running a protamine titration on normal blood with each new batch of protamine solution.
- (e) Biologic variations that may occur in preparation of heparin. It is advisable to check each new vial of heparin with the previous vial by running a protamine titration on normal blood using heparin from both vials before the supply from the one in use is exhausted.
- (f) Failure to obtain adequate mixing of either heparin with the original blood or of the heparinized blood with the protamine solutions. In the latter case clotting may appear sporadically in the series of protamine tubes.
- (g) Gelation. In some cases gelation precedes or substitutes for coagulation. This problem is best resolved by reading, as the end point, the tube in which gelation first appears.
- (h) Undiagnosed hemophilic or prothrombin deficient bloods. These conditions may increase the protamine titration; the complications are described in detail later.
- (i) Clotting within normal range (0.14 mg. of protamine) after one hour. As previously stated, normal blood and most abnormal blood specimens show no further clotting after one hour. An occasional blood sample, however, may show an increase in the protamine titration at the end of one hour but clot within the normal tube (0.14 mg. of protamine) after several hours. It has been our experience that these otherwise normal individuals show no significant clotting abnormality. In a few instances a similar decrease in the protamine titration occurred in bleeding cases but these generally did not return to the normal range.

*Factors Affecting the Protamine Titration*—Interpretation of the protamine titration depends upon complete evaluation of all the known factors concerned with hemostasis. Normal hemostasis involves at least three systems: (1) vascular, (2) cellular elements, (3) plasma. Of the cellular elements the platelets are probably the most important. They are concerned with thromboplastin and are intimately associated with the plasma factors which include prothrombin, fibrinogen, prothrombin accelerator factors, antihemophilic globulin, clotting inhibitors, and possibly others not yet known.

The protamine titration is independent of the platelet count and vascular components. When the protamine titration is increased, thrombocytopenia and vascular disturbances are frequently present. This association, however, is not one of cause and effect.

The protamine titration can be markedly influenced by any factor which is capable of prolonging the whole blood clotting time.

*Prothrombin Deficiency* Prothrombin deficiency of severe degree, in both dog and man, will increase the protamine requirement in the protamine titra-

This test is not necessarily a measure of heparin itself or even of heparinoid materials, for it may be increased by several factors, only some of which are known. Hence, it is only of value when all the known factors related to hemostasis can be evaluated. It appears to be a measure of a clotting defect similar to, though not identical with, that produced by the intravenous administration of a commercial beef heparin.

### *The Protamine Titration —*

#### *1 Reagents and Equipment*

- (a) Protamine (salmine) sulfate stock solution 50 mg of powdered protamine sulfate (Lilly) are dissolved in distilled water and made up to 50 ml in a volumetric flask. Do not use for twenty four hours. Keep refrigerated at 1 to 4° C (it is stable for one week)
- (b) Liquid commercial heparin (Abbott)
- (c) Ten serology tubes (1 cm inside diameter by 8 cm long)
- (d) Conical centrifuge tube graduated to 15 milliliters
- (e) 10 ml pipette, graduated to tip
- (f) 20 ml syringe, glass tipped, with thin coating of light mineral oil
- (g) 18 gauge needles, 1½ in long. These must be sharp and should be cleansed with Haemasol\* and checked with hydrogen peroxide for evidence of peroxidase before drying with alcohol and ether.

*All glassware must be chemically clean and dry before using*

#### *2 Procedure*

- (a) Pipetting the protamine solution. To each of the ten serology tubes the protamine sulfate solution is added from a micropipette in increments of 0.02 ml (0.02 mg) beginning with 0.02 ml (0.02 mg) in the first tube and ending with 0.20 ml (0.20 mg) in the tenth tube. The entire ten tube range runs serially from 0.02 ml to 0.20 ml (0.02 mg to 0.20 mg)
- (b) Pipette heparin into the conical tube. With a micropipette deliver 0.10 ml (10 mg) liquid commercial heparin to the bottom of the conical centrifuge tube.
- (c) Venipuncture. Cleanse skin with alcohol and dry. Apply tourniquet and make clean needle puncture. Gently aspirate (preferably by venous pressure) 12 to 14 ml of blood. If a good venipuncture is not accomplished on the initial puncture, another needle should be used as tissue juice or small amounts of blood may introduce serious error. The syringe should be free of air bubbles.
- (d) Mixing the blood and heparin. Remove needle from syringe and allow the blood to run gently down the side of the conical tube containing 10 mg (0.1 ml) of heparin, bringing the blood to the 11 ml mark. Stopper the tube with rubber stopper and slowly invert fifteen times to obtain reasonable mixing. The remainder of the test may be done in the laboratory and should be completed within one hour. If not pipetted at once, inversion mixing is repeated immediately before use.
- (e) Pipetting the blood. The 10 ml pipette is carefully filled with the heparinized blood mixture, avoiding aspiration of air bubbles. One milliliter of blood is allowed to flow down the side of each of the ten tubes containing the protamine solution. Each tube is shaken briskly eight to ten times to obtain reasonable mixing of the heparinized blood with protamine solution. The entire series of tubes is then allowed to stand undisturbed for one hour at room temperature before the end point is read. The end point is defined in terms of the protamine content of the tube containing the least amount of protamine in which a solid clot has formed at this time.
- (f) The end point. In a series of 100 normal male subjects all tubes containing 0.14 mg or more of protamine clotted. Those tubes containing 0.12 mg or less remained fluid.

## ENZYME STUDIES ON HUMAN BLOOD

### III EFFECT OF PLASMA PROTEINS ON COAGULATION\*

GEORGE Y. SHINOWARA, PH.D.  
COLUMBUS, OHIO

In a previous report<sup>1</sup> it was demonstrated that the level of the clotting times becomes elevated as the purity of the fibrinogen preparation increases. This observation prompted us to study the effect of proteins added to the substrate on the thrombin-fibrinogen reaction time.

#### METHODS AND MATERIAL

Fibrinogen fractions of 79 to 80 per cent purity were prepared from dried human plasma by the application of the low salt low temperature ethanol principle.<sup>2</sup> The hemoglobin solution was prepared by dialysis in citrate phosphate buffer (ionic strength 1/2, 0.129, pH 7.2) of lysed human erythrocytes previously washed four times with 6 vol of saline. All stock solutions, including those of Fractions II, III, IV 1, IV 4, V (Cohn<sup>3</sup>), and heated 25 per cent human albumin<sup>3, 4</sup> (Cutter Laboratories), were made up in citrate phosphate buffer on the day of the experiment. When adjustment to pH 7.2 was necessary, 0.1M NaOH in citrate phosphate buffer was added, volume not exceeding 10 per cent of the total volume of the stock solution. Each protein solution in at least four different concentration levels was added to fibrinogen fraction solutions at final substrate concentration of 0.5, 0.25, 0.125, 0.062, and 0.031 per cent. A control series without added protein was also tested. Thus, for one experiment, duplicate or triplicate clotting times were determined on each of at least twenty-five substrates. Actually, eleven experiments involving two hundred and seventy-five test solutions with primary plasma fractions added and fifty-five control solutions with fibrinogen fraction alone were done. In addition, fifteen test solutions with varying proportions of Fraction V (albumin) and a globulin mixture of Fractions II, III, IV 1 and IV 4 were investigated. The clotting times were determined upon addition of 0.2 cc thrombin (a 1 to 10 dilution of Lederle's Hemostatic Globulin in citrate phosphate buffer) to 0.8 cc of the substrate equilibrated at 37.5° C. The reagents and techniques for clotting time and protein determinations have been described previously.<sup>1</sup>

#### RESULTS

The data on the effect of added protein on the thrombin-fibrinogen reaction at 0.25 per cent fibrinogen fraction concentration are presented in Fig. 1.

From the Department of Pathology, College of Medicine, The Ohio State University.  
Received for publication Jan. 27, 1949.

Plasma Fractions II, III, IV 1 and IV 4 were obtained through the courtesy of Dr. E. J. Cohn. They were prepared in collaboration between the Department of Physical Chemistry, Harvard Medical School, Boston, Mass., and the Division of Biologic Laboratories of the Massachusetts Department of Public Health from blood collected in collaboration with the American Red Cross. Fibrinogen fractions were prepared in this laboratory from dried normal plasma processed from blood obtained from volunteer donors enrolled by the American Red Cross.

tion The degree of reduced prothrombin activity must be of such magnitude that it will prolong the whole blood clotting time, hence, it must be less than 40 per cent of normal activity before the titration is increased Based on experience with the normal dog given Dicumarol, the protamine titration does not increase until the prothrombin activity is less than 25 per cent of normal It may be that some revision of these data will be required in cases of reduced prothrombin activity in the presence of liver disease, as this aspect of the problem has not been investigated Normal or near normal prothrombin activity has been interpreted to indicate lack of any marked disturbance of the accelerator factor (accelerator globulin, prothrombin A, factor V)

*Heparinization* The therapeutic intravenous heparinization (35 to 50 mg per single total dose) markedly increases the clotting time but at these levels does not appreciably affect the protamine titration in otherwise normal blood If, however, the protamine titration scale is made more sensitive, the effect of heparin therapy can be detected readily Moreover, the patient with prothrombin deficiency, given heparin may show an increased titration when neither the prothrombin deficiency nor the heparin alone is capable of increasing the protamine titration

*Hemophilia* Since in this disease the clotting time is prolonged, the protamine titration also may be increased This is probably a function of thrombin formation Not all hemophiliac persons show an increased protamine titration, but in severe exacerbation the titration is generally increased

*Fibrin* Fibrin is the end point read in the protamine titration, consequently, in the absence of fibrinogen, no end point can be read

*Thrombocytopenia* The titration in our experience has been more frequently normal than abnormal in idiopathic thrombocytopenia However, patients with thrombocytopenia and increased protamine titration have been clinically improved and then titration returned to normal without evidence of any increase in the platelet count<sup>2</sup>

The magnitude of the changes produced in the protamine titration by the factors listed has been minimized by (1) the range of protamine used (increase of 0.02 mg per tube), (2) brisk shaking of tubes to initiate clotting, and (3) reading the titration no sooner than one hour after mixing heparinized samples in protamine tubes

#### SUMMARY

#### DISCUSSION

The foregoing experiments demonstrate without doubt that albumin has an accelerating effect on the thrombin-fibrinogen fraction clotting time. That this effect might be due to a contaminating enzyme or globulin in Fraction V is untenable for obvious reasons. Similar quantitative results were obtained with albumin prepared by the reprecipitation of Fraction V and subsequent heating of the resulting 97 to 99 per cent albumin for ten hours at 60° C in the presence of the sodium salt of acetyl tryptophan.<sup>3,4</sup> This interesting relationship of albumin to the thrombin-fibrinogen fraction reaction merits further study. There is no justification from the data on hand to state that albumin influences thrombin activity per se for it is possible that the fibrinogen molecule itself might be involved, that a coagulant contaminant might be activated, or that there may be inhibition of anticoagulant substance, if present, in the fibrinogen fraction.

It must be stated that our results do not necessarily refute the opposite findings of Quick,<sup>5</sup> who suggested that a blood albumin fraction is antithrombic and is synergistic with heparin. Extensive and careful work by other investigators has essentially confirmed this concept.<sup>6</sup> Quick<sup>5</sup> clearly emphasized that this activity might well be a contaminant in the albumin fraction. This was confirmed by several workers,<sup>7, 8, 9</sup> who demonstrated that the antithrombic activity resides in albumin fractions but not in crystalline albumin. Moreover, previous workers were purposefully testing the effect of albumin fractions on thrombin as indicated by their incubation of the two substances before reaction with fibrinogen or plasma. In our experiments the protein was added to fibrinogen fraction solutions, and no significant changes were demonstrated when clotting times were done during a three-hour period after mixing. Another reason that our results cannot be adequately compared with those of previous investigators is that the methods for the preparation of the protein fractions were not the same. Finally, the fibrinogen fractions used in this study contained approximately 20 per cent globulins (other than fibrinogen). Antihemophilic globulin<sup>10</sup> and an active proteolytic enzyme<sup>11</sup> have been reported in fibrinogen fractions.

Fraction II-III definitely increased the thrombin-fibrinogen fraction clotting time. Deutsch<sup>12</sup> determined thrombin by the two-stage method on this prothrombin-rich Fraction II-III and concluded that the assay is difficult because of the presence of thrombin-inhibitors, which he states are of two possible types: one which inhibits prothrombin conversion and another which inactivates thrombin. Since in the present study calcium and thromboplastin were not added, it would seem that only the latter type of inhibitor could apply as a possible explanation. Deutsch and Gerarde<sup>13</sup> also found that gamma globulins, as well as albumin, do not alter the clotting times of rabbit plasma with added calcium and thromboplastin, beta globulins, however, were found to have a definite retarding effect. As with Fraction II-III in this study, Fraction IV-1 caused an elevation in the thrombin-fibrinogen clotting time. Fraction IV-4 caused a slight depression in the clotting time, this may be explained on the basis of its relatively high albumin content of approximately 15 per cent.<sup>2</sup> In general, our results would indicate that the net effect of native plasma globulins in normal distribution is to increase the thrombin-fibrinogen fraction reaction time.

The experiments with albumin-globulin mixtures of varying proportions substantiate the results from experiments on individual fractions and suggest a homeostatic balance between albumin and globulins within a wide range in respect to the fibrinogen fraction-thrombin reaction.

#### SUMMARY

In a system of fibrinogen fractions (79 to 80 per cent purity) in citrate-phosphate buffer (pH 7.2, 1/2, 0.129), albumin definitely lowers, Fractions II-III and IV-1 elevate, and Fraction IV-4 and hemoglobin slightly depress the clotting times. The significance of these findings with fibrinogen fractions prepared by the low salt-low temperature ethanol principle is discussed.

The valuable technical assistance of Mary Beth Everhart is gratefully acknowledged

## THE USE OF URINARY PIGMENT EXCRETION FOR THE MEASUREMENT OF BASAL METABOLIC RATE

JEFFERSON J. VORZIMER, M.D., F.A.C.P., IRA B. COHEN, M.D., AND  
JULES JOSKOW, B.S., M.A.\*  
NEW YORK, N. Y.

THE diagnosis and control of hyperthyroidism depends, to a large degree, upon an accurate determination of the basal metabolic rate. It is known that such conditions as neurocirculatory asthenia, alcoholism, pregnancy, and apprehension may cause an increase in oxygen consumption which does not reflect the true basal metabolism. In pediatric practice, and in patients without teeth or with perforated eardrums, it is virtually impossible to obtain accurate B.M.R. determinations with the usual clinical equipment. The existence of these conditions which produce an increase in oxygen consumption rate, in the absence of an increased basal metabolism, frequently renders the accuracy of the B.M.R., as determined by the respiratory calorimeter, open to question. Since the determination of the true basal metabolism, and not a machine-measured increase in oxygen consumption, is of great importance in the diagnosis and control of thyrotoxicosis, the presence of any of the afore-mentioned conditions frequently makes it impossible to determine true basal metabolism, with our present methods. The elaboration of a clinically applicable procedure, which would serve as a measure of basal metabolism, independent of oxygen consumption, is, therefore, of great importance. Early in 1948, Dr. Irwin Slater brought to our attention the work of Ostow and Philo, on the relation of the pigment/creatinine ratio to basal metabolic rate. We investigated the accuracy and constancy of this relationship, in an effort to obtain a relatively simple yet practical and accurate measure of true basal metabolism.

The yellow color of the urine is generally ascribed to the pigment urochrome. The chemical constitution and the nature of the precursors of urochrome are unknown, although there is evidence<sup>1</sup> that tryptophane and kynurenin are involved in its production. Diabkin<sup>2</sup> observed that the output of urinary pigment is remarkably constant from day to day under ordinary conditions of health. This output is independent of diet, but bears a relation to the level of basal oxygen consumption, and is, therefore, a product of endogenous metabolism. In hyperthyroidism, fevers, and in artificially produced elevations of metabolism by the administration of thyroxin or epinephrine, the output of urinary pigment is increased. Urochrome excretion also is enhanced by tissue breakdown, starvation, or by the administration of acids. Diminished urinary pigment excretion is observed after extirpation of the thyroid, and the administration of alkalis.

From the Medical Service of Beth Israel Hospital.

Aided by a grant from Mr. Samuel Koenig.

Received for publication Dec. 24, 1948.

\*Department of Statistics and Economics, The City College of New York.

The daily creatinine excretion is extraordinarily constant for the individual and is not influenced by ordinary exercise or by urine volume. Creatinine output varies from 1.5 to 2.0 Gm daily for men and from 0.8 to 1.5 Gm for women, corresponding to about 2 per cent of body creatine content. The creatinine coefficient

$$\frac{\text{Mg creatinine excreted/day}}{\text{Body weight in kilograms}}$$

is from 20 to 26 for the majority of normal men and from 14 to 22 for women. Its value depends upon the muscular development of the individual; the sex variation is due presumably to the different relative amounts of fatty and muscular tissues of male and female bodies. Athletic women for this reason have a coefficient as high as or higher than men of obese build and poor muscular development.<sup>3</sup> Unlike the excretion of urea which is derived largely from exogenous sources, the creatinine output is practically independent of the protein level of the diet and is therefore considered to be a quantitative index of tissue and more especially of muscle metabolism.

Ostow and Philo<sup>4</sup> reinvestigated the nature of the relationship between urinary pigment output and the basal metabolic rate. To correct for weight, height, habitus, and age of the subjects, the rate of pigment excretion was compared with the rate of excretion of creatinine, the latter being constant for each individual. Since this is a ratio of the concentration of the two substances, there is no necessity for measuring urinary volumes per unit of time. This ratio (pigment/creatinine) was found to parallel the basal metabolic rates of patients to whom thyroid extract was administered. The test cannot be done in the presence of bile or free hemoglobin in the urine such as may occur during menstruation, nor following the ingestion of foods such as beets and rhubarb or large quantities of riboflavin or dyes which color the urine. In cases of renal disease with nitrogen retention<sup>2</sup> and in cases of severe liver damage and in some cases of chronic heart disease it is impossible to obtain a valid pigment/creatinine ratio. From a practical standpoint, however, these conditions do not usually coexist in patients in whom it is of importance to obtain an accurate basal metabolic rate determination for diagnosis or management.

The purpose of this investigation was to determine whether there existed an accurate correlation between basal metabolic rates as determined by the respiratory calorimeter and the pigment/creatinine ratio and if possible, to obtain a regression equation from this relationship. If a statistically valid equation could be derived, the pigment/creatinine ratio could then be applied wherever the accuracy of the basal metabolic rate measurement was in question.

#### METHOD

Patients selected for this study were instructed to report to the clinic as soon as possible after arising. On arrival they voided urine and this specimen was discarded. After resting for one hour a B M R determination was done with the respiratory calorimeter. The pigment/creatinine ratio then was determined on a urine sample obtained after the completion of the B M R test. Only those cases in which the B M R was consistent with the clinical diagnosis

were included in this study. To prevent variations in the apparent concentration of urinary pigment due to chemical alteration after voiding, all samples of urine were placed immediately in a refrigerator, and spectrophotometric readings were made as soon as possible, though never later than two hours after voiding. The urine sample is centrifuged at high speed for ten minutes to remove any sediment. A portion of the supernatant urine is then placed in a 10 by 75 ml cuvette and the per cent light transmission at a wave length of  $420\text{ m}\mu$  is determined with a Coleman Junior spectrophotometer.

Fig. 1

The urinary creatinine content is determined by a modification of the Jaffe reaction<sup>6</sup>. Urine, 0.1 ml, diluted 1:5 with distilled water (1:4 in urines of low specific gravity), 2 ml of saturated picric acid, and 0.15 ml of 10 per cent sodium hydroxide are placed in the 10 by 75 ml cuvette. After standing for ten minutes, the per cent light transmission at a wave length of  $520\text{ m}\mu$  is determined in the spectrophotometer. The creatinine concentration is determined from a graph made by plotting per cent light transmission against various dilutions of a standard creatinine solution.

#### RESULTS

Determinations obtained from one hundred fifty-six adult female subjects are indicated in Fig. 1, and from fifty-seven adult male subjects in Fig. 2.

It will be noted in Figs. 1 and 2, that the great majority of both female (ninety-four cases) and male subjects (thirty-three cases) exhibit basal metabolic rates generally considered to fall in the normal range (15 per cent above and 10 per cent below the calculated normal). From a statistical standpoint the number of cases above the normal range (forty-one female subjects, seventeen male subjects) is large enough and correlates well with the findings in the

normal group. It would therefore seem that the curve is applicable to hyperthyroid states. The cases that fall below the normal range (twenty one female subjects, seven male subjects) are too few in number to allow any definite conclusions as to the application of the curve in hypothyroid states.

Statistical analysis of the one hundred fifty six observations on women revealed the following results. B M R readings varied from 72 per cent of normal to 162 per cent, with a mean of  $108 \pm$  per cent and a standard deviation of 18.8

Fig. 2

per cent. Pigment/creatinine readings ranged from 124 to 536 averaging 243.8, with a standard deviation of 80.2. The coefficient of correlation, assuming a straight line relationship, was 0.92. The standard error of estimate was 7.4 per cent. The regression line is  $B M R = 54.7 + 22 \text{ pigment/creatinine}$ .

Statistical analysis upon the fifty seven observations on men revealed the following results. B M R readings varied from 83 per cent to 159 per cent averaging 109.9 per cent, with a standard deviation of 15.0 per cent. Pigment/creatinine readings ranged from 124 to 394 with a standard deviation of 52.2. The coefficient of correlation of Pearson was 0.88. The standard error of estimate was 7.1 per cent. The regression line is  $B M R = 57.0 + 25 \text{ pigment/creatinine}$ .

#### INTERPRETATION OF DATA

*Women*.—The calculation of the coefficient of correlation reveals an extremely close relationship between B M R and pigment/creatinine. The 0.92 coefficient of correlation implies a relationship close enough to allow interchangeability of the variables. The regression equation obtained is quite close to the one obtained by Ostow and Philo,<sup>4</sup> thus confirming their results. However, the higher correlation in our analysis imputes even greater reliability to the use

of the equation. Graphically, this fact is illustrated by the smaller scatter of points around our regression line.

*Men*—Ostow and Philo<sup>4</sup> published no scatter diagrams for data on men, but it can be inferred that the relationship which they discovered was too weak for practical application. However, upon applying the correlation technique to our fifty-seven determinations, we do uncover a strong relationship between the two variables. While not quite as closely related as the variables for the data on women, the coefficient of correlation (0.88) certainly indicates a strong enough relationship for the application of the regression technique. In this instance, it should be noted that our regression equation differs quite significantly from the results obtained by Ostow and Philo,<sup>4</sup> but is very close to the results obtained in the female series. Further experimental and statistical investigation would very likely reveal that the results for the male group are not significantly different from those for the female group.

#### CONCLUSION

The ratio of urinary pigment to creatinine excretion in the urine can be used as a measure of basal metabolism. The test is easily performed and is reliable.

The basal metabolic rate can be calculated from the following equations:

$$\begin{aligned}\text{Men—BMR} &= 57.0 + 25 \text{ pigment/creatinine} \\ \text{Women—BMR} &= 54.7 + 22 \text{ pigment/creatinine}\end{aligned}$$

The authors appreciate the technical assistance rendered by Miss Virginia Rehmertzer, Miss Edna Arzt, and Mrs. Jennie Shotton.

## EXACERBATION OF ALLOXAN DIABETES IN MICE BY INJECTION OF TYPHOID VACCINE    ROLE OF THE ADRENAL GLAND

LOUIS TOBIAN, JR., M.D. AND W. L. JACK EDWARDS, M.D.  
DALLAS, TEXAS

**I**NFECTIONS as well as other forms of stress, cause the mammalian organism to increase the rate of adrenal cortex secretion. Evidence for this increased secretion in man includes (1) adrenal cortex hypertrophy,<sup>1</sup> (2) depletion of cholesterol in the adrenal cortex,<sup>1, 2, 3</sup> (3) increased urinary excretion of steroids with adrenal cortical activity,<sup>4, 5, 6</sup> and (4) decrease in the lymphocytes and eosinophils in the peripheral blood.<sup>7, 8</sup>

Hypersecretion of the adrenal cortex, as seen in Cushing's syndrome, is associated with a diabetic syndrome which is particularly resistant to insulin. Hyperglycemia and glycosuria can be induced in both man and animals by injection of purified pituitary corticotrophic hormone.<sup>9, 10, 11</sup> 11 oxy corticosteroids injected into normal force fed rats have been shown to produce glycosuria.<sup>11</sup> Administration of pituitary corticotrophin,<sup>1</sup> adrenal cortical extract,<sup>12</sup> or 11 oxy corticosteroids<sup>13</sup> to diabetic rats greatly increases the glycosuria. Ingle has marshalled evidence that the glycosuria produced in rats by corticotrophic hormone or 11 oxy steroids is chiefly the result of a decreased utilization of glucose.<sup>11</sup>

Colowick, Cori, and Sleim have shown that adrenal cortical extract inhibits the hexokinase enzyme system of diabetic rat muscle but not that of normal rat muscle.<sup>14</sup> Moreover, it is well known that this hexokinase reaction is one of the main determinants of the rate of glucose utilization. These findings suggested that the exacerbation of diabetes seen during infections and trauma might be due to an increased secretion of the adrenal cortex with a resulting decrease in glucose utilization.

The following experiment was designed to investigate this possibility.

### METHODS

Following a twelve hour fast, albino mice weighing around 20 grams were given 275 mg of alloxan per kilogram of body weight, subcutaneously. Food was placed in their cages three hours after the alloxan injection. The mice which survived the alloxan injection then were divided into two groups. The mice of Group I were adrenalectomized bilaterally, ten days after their alloxan injection. Following the adrenalectomy each mouse in this group was given adrenal cortical extract (0.05 cc of Upjohn's Lipo Adrenal Cortex) subcutaneously, at eleven hour intervals all through the entire experiment.

Group II consisted of mice whose adrenals were left intact. These mice received 0.5 cc of corn oil at eleven hour intervals all through the entire experiment, corresponding to the injection of adrenal cortex extract in Group I.

From the Department of Internal Medicine, Southwestern Medical College.  
Received for publication, Sept. 9, 1948.

Twelve days after the mice in Group I had been adrenalectomized, the mice in both groups were fasted eight hours, and a blood sugar estimation was made on a 20 c mm sample of tail blood

Two, ten, and sixteen hours after blood had been drawn for the blood sugar determination, each mouse in both groups received, intraperitoneally, 250 million killed typhoid organisms suspended in 2 c c of 10 per cent dextrose in normal saline solution Six hours after the last injection a 20 c mm tail blood sample again was drawn for a blood sugar estimation No solid food was permitted between the blood sugar determinations, but water was available as desired throughout the experiment The adrenal cortex extract (Upjohn) for Group I and the corn oil injections for Group II were continued as scheduled during the typhoid injections Each fasting blood sugar was drawn five hours after an injection of either adrenal cortical extract or corn oil

Blood sugar concentration was determined by the Somogyi procedure<sup>14</sup> The reduced copper was determined with Nelson's arsenomolybdate reagent<sup>15</sup> The final solutions were read in an Evelyn colorimeter (filter No 660) Reagent blanks and glucose standards were run with each determination Certain additional control studies, as indicated later, were also performed

In designing these experiments it was assumed that the level of the fasting blood sugar is a valid index of the severity of diabetes Mice were considered diabetic if a fasting blood sugar was over 125 mg per cent Only mice that were actually diabetic were included in the experimental Groups I and II

#### RESULTS

The percentage in each group of mice that showed an increase in fasting blood glucose level after the completion of the typhoid injection is shown in Table I It can be seen that there is no significant difference between the two groups

TABLE I EFFECT OF TYPHOID VACCINE ON THE BLOOD SUGAR OF DIABETIC MICE

	NUMBER OF MICE IN GROUP	NUMBER OF MICE IN GROUP SHOWING A RISE IN FASTING BLOOD SUGAR AFTER TYPHOID VACCINE	MICE SHOWING A RISE IN FASTING BLOOD SUGAR AFTER TYPHOID VACCINE (PER CENT)
Group I (Adrenalectomized)	13	10	77
Group II (Adrenals intact)	17	13	76.5

In Table II, the milligrams per cent increase of blood sugar of each of the mice who showed a rise after typhoid is tabulated along with the average for each group

The results, when analyzed statistically, show that there is no significant difference between the increase in blood sugar of the two groups ( $P$  value = .8)

Further control studies showed the following

1 That the injections of adrenal cortical extract, in the amount we used, did not raise the blood sugar to diabetic levels in adrenalectomized nondiabetic mice (see Table III)

#### DISCUSSION

The experimental findings showed that adrenalectomized mice receiving a fixed daily amount of adrenal cortex extract exhibited as great a rise in fasting blood sugar after a course of typhoid injections as mice with intact adrenals. Since these adrenalectomized mice were incapable of increasing their own adrenal hormone secretion, it is concluded that adrenal hypersecretion (either adrenal cortex or medulla) was probably not the cause of the elevation of blood sugar produced by typhoid vaccine injections in these diabetic mice.

It is possible that accessory adrenal tissue had begun to function in these adrenalectomized mice, but they began receiving adrenal cortex extract immediately following adrenalectomy and hence had little stimulus for the growth of accessory adrenal tissue. Following the experiment, no more adrenal cortex extract was given, and all of the adrenalectomized mice died in a few days. If many had had significant amounts of accessory adrenal tissue, one would have expected more survivors.

If one is justified in applying such experiments to the problem of infections in diabetic patients, it would appear that increased adrenal activity is not the cause of the aggravation of clinical diabetes by infections.

It may be justifiable to speculate on other possible explanations of the exacerbation of diabetes with infections.

It is possible that the anterior pituitary hormone which inhibits the hexokinase reaction<sup>17</sup> is secreted in increased quantities during infections and stress, and that the hypersecretion of this hormone causes decreased glucose utilization and hence an exacerbation of diabetes. This possibility is supported by the observation that the anterior pituitary gland secretes an increased amount of another hormone, the corticotrophic hormone, in response to stress.<sup>2</sup>

Kun<sup>18</sup> has recently reported that meningococcal endotoxin causes *in vitro* a decrease in glucose utilization by rat muscle extracts, probably by inhibiting the hexokinase system. This inhibition of glucose utilization did not occur if Zn-free insulin was added to the reaction mixture. It may be that the endotoxins of various other types of bacteria cause an inhibition of the hexokinase system, with a resulting decrease of glucose utilization.

In diabetes mellitus, glucose utilization for a given level of blood sugar is considerably decreased, and any mechanisms, such as the two mentioned, which

further impair glucose utilization will cause a marked exacerbation of the manifestations of diabetes, such as hyperglycemia, glycosuria, and excessive mobilization of fat for energy metabolism

#### SUMMARY

The exacerbation of diabetes in mice following typhoid injections is not caused by an increased secretion of either medullary or cortical hormones of the adrenal gland. If one is justified in applying this finding to comparable clinical situations, the exacerbation of clinical diabetes during infections probably also is not caused by adrenal hypersecretion.

We wish to thank Dr. E. Gifford Upjohn, of the Upjohn Company, Kalamazoo, Mich., for generously supplying us with Lipo-Adrenal Cortex (Upjohn).

## HYPERGLYCEMIA AND GLUCOSURIA FOLLOWING THYROID ADMINISTRATION IN ALLOXAN TREATED RATS

DAVID W. MOLANDER, M.S., M.D.,\* AND ARTHUR KIRSCHBAUM, M.D., PH.D.  
MINNEAPOLIS, MINN.

SHPLEY and Rannefeld<sup>1</sup> showed that the glucose tolerances of rats which received small repeated doses of alloxan were similar to those of diabetic animals. Histologic study of islet tissue in rats injected intravenously every other day four times with 20 mg per kilogram doses of alloxan revealed apparently intact islets of Langerhans with the methods used.<sup>2</sup> Glucose tolerances in these animals were decreased. It was concluded that functional impairment of the beta cells may be caused by small repeated doses of alloxan.

Animals with islet tissue functionally altered by alloxan were fed thyroid in this experiment to determine if histologic changes would take place. One group of rats was adrenalectomized to determine the influence of lowered blood sugar level on islet tissue in alloxanized-thyroid fed animals.

### MATERIALS AND METHODS

Four groups of white albino rats of the same stock and age, weighing about 100 grams, and of mixed sex were used. Animals in the first three groups received four intravenous injections of alloxan (20 mg per kilogram), one every other day. Group 4 animals were controls and did not receive alloxan. Fasting blood sugars in all animals were within 80 to 120 mg per cent using a modified Folin Wu procedure.<sup>1</sup> Glucose tolerances determined ten days after the last injection of alloxan were impaired in the first three groups. Group 4 had normal glucose tolerances. Glucose tolerance tests were conducted by withdrawing a sixteen hour fasting blood sample, injecting 0.5 Gm per kilogram glucose intravenously in 20 per cent solution, and drawing blood samples at one half, one, and two hour intervals. Pancreatic biopsy revealed normal islet tissue with the methods used. Animals in Group 3 were adrenalectomized and given 1 per cent saline to drink. Animals were then tube fed powdered thyroid (Armour), 0.1 Gm per kilogram in water, daily for one month. Body weights of the animals were followed. All animals were allowed to eat ad libitum a prepared dog biscuit.

Following this treatment, twenty four hour urine specimens were examined for glucose.<sup>†</sup> Animals were placed in metabolism cages for forty eight hours and tube fed three times a day 8 cc of a diet containing 20 per cent protein, 76 per cent carbohydrate, 4 per cent fat, adequate salts and vitamins. Each cubic centimeter of diet contained 182 large calories per milliliter. This diet was a modified one of a type suggested by Dr. R. Reinecke, Department of Physiology. Glucose tolerances were also repeated. These procedures were done three weeks after the last dose of thyroid. All animals were sacrificed without starvation, at the same time, one month after the last thyroid feeding, and the pancreases were placed in Bouin's fixative. The tissue was sectioned at 4 microns. After staining with Heidenhain's iron hematoxylin, every tenth section was examined and the number of alpha and beta cells counted and the size of the islet noted.

From the Department of Anatomy University of Minnesota Medical School.

This investigation was supported by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health United States Public Health Service. Received for publication Jan. 24, 1949.

‡Quantitative Benedict's method.

## RESULTS

Glucosuria and fasting hyperglycemia occurred in animals that were fed thyroid following four small repeated doses of alloxan (Tables I, II, and III). These animals were observed for a month after termination of thyroid administration and the glucosuria remained. Microscopic examination of islets in these animals revealed a reduction in the number of beta cells (Table IV). In animals that received alloxan only and were followed for a comparable length of time, no spontaneous hyperglycemia occurred (Tables I and II). Glucose tolerance curves of normal rats, four dose alloxan animals (20 mg per kilogram), and four dose alloxan animals which were fed thyroid in addition (0.1 Gm per kilogram) are shown in Fig 1. Islets in animals which received alloxan only appeared normal. Similarly, in animals which received only thyroid, no hyperglycemia, glucosuria, nor histologic alteration of the islets appeared with the methods used (Tables I and II).

In the group that was adrenalectomized following alloxan and then fed thyroid, no clinical diabetes developed (Tables I, II, and III), nor were any changes in the islets noted. It would appear that a lowering of blood sugar might have been the protective mechanism in this group.

In the alloxanized thyroid fed animals which developed clinical diabetes, it would seem that the initial functional impairment of the beta cells by alloxan was essential if thyroid feeding produced hyperglycemia, glucosuria, and reduction in the number of beta cells.

Since the beta cells are centrally located within the rat islet alpha cells being present only at the periphery, evaluation of beta versus alpha cell damage is unequivocal. The beta cells of the rat are larger than the alpha cells, and on the basis of size, position, and affinity of the beta cell granules for hematoxylin, counts of the cell types can be made readily on thin sections stained properly with non hematoxylin and eosin. Identification of cell types was checked against Bouin fixed material stained by the method of Gomori.<sup>2</sup> In the animals fed thyroid following the four small doses of alloxan, the islets were smaller (fewer beta cells) and the alpha cells were not confined to the periphery as in the case of islets from either untreated rats or animals which received only the four small doses of alloxan, or were fed thyroid with no other treatment, or were fed thyroid but were adrenalectomized following alloxan.

TABLE I. HYPERGLYCEMIA AND GLUCOSURIA FOLLOWING ALLOXAN AND THYROID

### COMPARATIVE GROWTH CURVES

Fig 2

Thyroid effect on body weight is seen in the comparative growth curves (Fig 2). Animals which received only alloxan in small amounts gained in body weight at a rate similar to normal animals, however, the group that received thyroid in addition to alloxan was retarded (Fig 2). Animals which received only thyroid for a month were transiently stunted in growth.

### SUMMARY

Rats given four small doses of alloxan (20 mg per kilogram) and then fed thyroid daily for one month (0.1 Gm per kilogram) developed hyperglycemia

and glucosuria. Islets in these animals showed a reduction in the number of beta cells. Retarded growth occurred.

Animals given alloxan but no thyroid and followed a similar length of time showed neither hyperglycemia nor glucosuria, and islet tissue appeared intact with the methods used. Growth retardation was not noted.

Animals which received only thyroid for a similar period were retarded in growth, showed neither hyperglycemia nor glucosuria, and had normal-appearing islet tissue.

The small group that was adrenalectomized following alloxan injection and then fed thyroid did not develop hyperglycemia, glucosuria, nor show any islet changes. Lower blood sugar level (reduced gluconeogenesis) following adrenalectomy may have been a factor in inhibiting beta cell damage.

By functionally altering the beta cells with small repeated doses of alloxan and then feeding thyroid it was possible to detect the added metabolic strain of thyroid on islet tissue.

## THE EXCRETION OF PENICILLIN IN HUMAN MILK

R. ROZANSKY, M.D., AND A. BRZEZINSKY, M.D.  
JERUSALEM PALESTINE

THE extensive literature dealing with the concentrations of penicillin in body tissues and fluids following intramuscular administration contains few references to the fate of penicillin in human milk. Seeley and co-workers<sup>1</sup> found no penicillin in bovine milk after injecting 500,000 units. Greene and associates found a concentration of 0.015 to 0.06 unit per cubic centimeter in human milk after a single intramuscular injection of 100,000 units of penicillin. In view of the scarcity of the data a study of the excretion of penicillin in human milk was undertaken.

### MATERIALS AND METHODS

The concentration of penicillin was determined by the serial dilution method of Kolmer.<sup>2</sup> Each series consisted of six tubes with a final dilution of 1:32. One tenth of a cubic centimeter of a 1:1,000 dilution of a twenty-four hour bouillon culture of *Staphylococcus aureus* (Heathley strain) was added to 1 c.c. of the medium.

Since the opacity of milk precluded observations on turbidity we estimated growth inhibition with the aid of color indicators. Whereas methylene blue is suitable for the estimation of penicillin concentration in bovine milk, since the reduction of the dye and the coagulation of the milk yield a clear end point in the case of human milk we found bromthymol blue to be a more suitable indicator. Human milk normally has a pH of 7.1 to 7.6. Bromthymol blue changes color from blue to green at pH 6.6, and turns yellowish at pH 6.0.

The indicator was made up as follows: Bromthymol blue, 1.0 Gm. NaOH N/10 25 c.c., aqua destillata, 475 c.c. 12 c.c. of indicator per 1 liter of medium.

Whenever possible, the dilutions were made up with milk from the same donor. In a few cases when only a small quantity of milk was obtainable dilutions were made up with milk from another woman. Milk was taken before the injection of penicillin and was boiled for five minutes to ensure sterility. It was found that a 1:10 dilution of milk in normal saline could replace whole milk as a satisfactory diluent, without inhibiting the growth of the test organism. In consequence of this observation both whole milk and milk saline were regularly employed as diluents in parallel series.

We observed that when we added a few drops of 0.1N NaOH to the medium, we obtained clearer color distinction. The slight alkalization enhances the blue color and at the same time promotes the growth of the staphylococcus. To test the reliability of the color changes, we inoculated agar slants from the dilution series and observed that all dilutions that had not turned green had remained sterile. Readings were made after twenty-four hour incubation at 37°C. The penicillin sensitivity of the test strain was examined with each experiment. The strain was sensitive to 0.03 unit per cubic centimeter and yielded the corresponding color changes. Milk in itself does not destroy the antibiotic activity of penicillin in vitro since we found that solutions of penicillin in milk had the same antibiotic action as did corresponding solutions in normal saline.

In a preliminary experiment to determine whether penicillin is excreted in milk, we examined the milk of a bitch weighing 18 kilograms three days after whelping. A single intramuscular injection of 100,000 units diluted in 2 c.c. normal saline was given in the thigh. Milk was taken before the injection and at intervals of one, two and four hours after the injection. The sample taken before penicillin injection had no antibiotic activity,

Received for publication Dec. 10, 1948.

whereas varying amounts of penicillin appeared following the injection (0.12 unit per cubic centimeter after one hour, and 0.24 unit per cubic centimeter after two and four hours)

We studied penicillin concentration in human milk in the following manner. A single intramuscular injection of 200,000 to 600,000 units of penicillin (crystalline G, potassium salt) dissolved in normal saline was administered to thirteen women two to eight days after delivery. The injection was given as soon as the infant was taken from the breast. In one instance, four additional injections of 30,000 units each were given at three hour intervals before and after the main injection of 400,000 units. Milk samples for the determination of penicillin concentrations were taken before the injection and one, two, four, and six hours after the injection. On three occasions, samples of milk taken nine hours after the injection were also examined. All samples were taken from the same breast. Before withdrawing the milk, the nipple and surrounding area were cleaned with iodine, washed with alcohol, and dried with a sterile towel. For purposes of comparison a number of blood samples were also taken two and six hours following injection. In each case sterility tests of the milk were done, and contaminated samples were discarded. Control experiments were regularly carried out to prove that the milk taken before the injection of penicillin possessed no antibiotic properties.

### RESULTS AND DISCUSSION

The results of the study are summarized in Table I.

TABLE I. CONCENTRATION OF PENICILLIN (U/C C) IN MILK AND SERUM FOLLOWING INTRAMUSCULAR ADMINISTRATION

CASE SERIAL NO	DAYS AFTER DELIVERY	DOSAGE (UNITS)	HOURS AFTER INJECTION								REMARKS
			1	2		4	6		9

≥ More or equal < less than — not examined

As may be seen from the table, significant quantities of penicillin were found in the milk following intramuscular injection, in all but one of the cases studied (Case 5). Within one hour after injection, penicillin was found in appreciable quantities, the maximum concentration observed having been 0.36 unit per cubic centimeter. Two hours after the injection, the level was in most cases twice as high as after one hour, and it was still rising steadily at four hours. This rise in concentration was observed in almost every instance. The penicillin concentration began to fall six hours after injection, but remained as high as the one-hour level, or higher. Nine hours after injection, penicillin was still present in the milk of two of the three patients examined at this time. In Case 13, in which the patient had received injections of 30,000 units every three

hours, in addition to the main injection of 400 000 units, the level was maintained at 0.48 unit per cubic centimeter throughout six hours. In Case 5 although the dose injected was large, and although the penicillin level in the serum was high (0.96 unit per cubic centimeter), no penicillin could be detected in the milk.

## Average Values Of Penicillin Levels In Human Milk

Fig 1

The steady increase and persistence of penicillin in human milk during the first four hours after intramuscular injection, followed by subsequent gradual decrease, is clearly demonstrated in Fig 1.

As for the relationship between the levels of penicillin in serum and milk we found that at the end of two hours the concentration of penicillin in the milk was 10 to 15 per cent of that in the serum. Subsequently the milk level remains constant or rises, while the blood level falls. In milk as in serum, no close relationship exists between the dose of penicillin injected and the level obtained, but in general higher penicillin levels were observed after larger doses. The results of this study explain the beneficial therapeutic effects of intramuscularly injected penicillin on mastitis. The penicillin sensitivity of most penicillin susceptible strains of bacteria encountered in this country, as examined by Gurevitch,<sup>4</sup> lies within the range of the levels we have demonstrated in milk.

Whether suckling milk containing penicillin can favorably affect oral infections in the infant, caused by organisms sensitive to penicillin, is a question requiring investigation.

## SUMMARY

A study was made on the penicillin concentration in milk of thirteen women after intramuscular administration of the drug. Significant quantities of penicillin were found in the milk of twelve of these subjects.

Penicillin was found in milk one hour after the injection. Up to four hours after the injection the level rose, followed by a gradual fall in the concentration.

In two of three subjects examined, penicillin was still found nine hours after the injection.

We are indebted to Dr. N. Grossowicz for his helpful advice.

## BACTERIMETRIC STUDIES III BLOOD LEVEL STUDIES ON TEROPTERIN METABOLISM

G. TORRANES, PH.D., AND D. L. GALLANT, A.B.  
PHILADELPHIA, PA.

THIS work was undertaken because of the evident potentialities of teropterin in cancer therapy.<sup>1</sup> The approach is based on two premises: (a) the observed clinical effects of teropterin treatment seem to cover the whole range from apparent ineffectiveness, and possibly stimulatory tendencies, to genuine regressions of malignant growths, and (b) in view of what is known about individual variations in vitamin metabolism it seems possible that individual differences in the metabolic handling of teropterin play an important role in determining its clinical effectiveness.

Because of available evidence indicating rapid metabolic liberation of folic acid (folic acid, pteroylglutamic acid) from teropterin (pteroylterglutamic acid) and because of the presumptive procarcinogenic activity of the former,<sup>2</sup> it seemed desirable to determine the blood concentrations of these two compounds resulting from administration of teropterin.

### METHOD

A simplified analytic method has been developed for this work which is based on the well established differences<sup>4</sup> in the growth responses of *Lactobacillus casei* 7469 and *Streptococcus faecalis* 8043 (*St. lactis* R) to the two compounds. The experimental procedure is briefly as follows:

Blood samples of approximately 0.015 cc are taken from the finger tip in a Thoma leucocyte diluting pipette and after dilution with 20 volumes of water are placed in capped vials and stored in a freezing compartment until they are analyzed.

For the bacterimetric determinations a single basal medium of low folic acid content is used for both organisms. This medium is based on the *L. casei* medium of Teply and Elvehjem<sup>5</sup> differing from the latter in that vitamins (using pyridoxamine) and phosphates are present according to the specifications of Roberts and Snell,<sup>6</sup> and in that casein hydrolysate and peptone are replaced by vitamin free enzymatic casein hydrolysate\* in an amount of 0.12 cc per cubic centimeter of finished medium. Culture tubes and the procedures of sterilization, inoculation, incubation and photoelectric turbidity measurement are those described by us elsewhere,<sup>7</sup> except that readings were taken at 675 m $\mu$  and the tubes contained only 6 cc of solution. This volume is sufficient if the tubes are slightly raised in the Coleman cuvette carrier by means of a fixed support.

Nutritional Biochemicals Corporation, Cleveland, Ohio.

For purposes of convenience in measuring, calculating, and recording, the one trillionth part of a mol ( $1 \times 10^{-12}$  mol), called briefly 1 trillionmol and abbreviated 1 tM, has been adopted as a reference unit for the present work with the pteroyl compounds. It corresponds to 0.441 millimicrogram of pteroylglutamic acid or 0.699 millimicrogram of pteroyltriglutamic acid.

Inocula of the two organisms are grown in a medium which contains, per liter, 20 Gm Bacto-casitone, 5 Gm Bacto-peptone, 20 Gm anhydrous sodium acetate, 20 Gm glucose, 2.5 Gm each of  $\text{KH}_2\text{PO}_4$  and  $\text{K}_2\text{HPO}_4$ , 200 mg  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , and 10 mg each of  $\text{NaCl}$ ,  $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$ , and  $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ . If this medium is inoculated from a culture of either organism freshly grown in the same medium, active inoculum cultures are obtained after approximately sixteen hours at 37 to 38°. The cells are washed once with water and diluted to an O.D. of 100.

The standard series consist of single tubes containing 0, 0.15, 0.30, 0.45, 0.60, 0.90, 1.20, and 1.50 tM folacin for *L. casei* and twice these quantities for *St. faecalis*. Determinations performed under these conditions indicate a ratio of approximately 1 for the molar activities of folacin and teropterin for *L. casei*, and for *St. faecalis* an activity of teropterin of approximately 2 per cent of that of folacin. In the actual determinations only folacin standards, for both organisms, have been run and, as a practical approximation, the *L. casei* results of the unknown have been considered as the measure of the sum of folacin and teropterin, and the *St. faecalis* results as the measure of folacin.

For analysis the original 1:21 blood dilutions are treated as follows. A 0.10 c.c. portion is further diluted with 9.4 c.c. of water. In order to minimize subsequent interference of turbidities arising from blood proteins, these dilutions are autoclaved at 120° for two and one-half minutes and, after cooling, centrifuged. For each blood specimen four assay tubes are then set up, containing 0.5 and 1.0 c.c. of the 1:2,000 dilutions for *L. casei*, and 1.5 and 3.0 c.c. for *St. faecalis*. Volumes are completed to 6 c.c. with inclusion of 3 c.c. of the basal medium. Because in some cases small residual turbidities remain after the preliminary autoclaving and centrifugation, initial optical density readings are taken on all tubes after the final sterilization. These readings are subtracted as blanks from the subsequent readings, taken after sixteen and twenty-two hours of incubation of the inoculated tubes at 37.7°. The practice of taking readings at two time levels, as well as two quantity levels, was adopted as an additional means of guarding against possible errors arising from unknown growth factors.

## RESULTS

The results obtained so far are summarized in the seventeen charts of Fig. 1 (1 to 15) and Fig. 2 (16 and 17). The full lines show the blood concentrations found for folacin and the broken lines show the concentrations of teropterin. The units of the ordinate, which in all instances are drawn to the same scale, are trillionmols per cubic centimeter of blood. The abscissa units are hours. Except for charts 13, 16, and 17, then scaling is also uniform. The

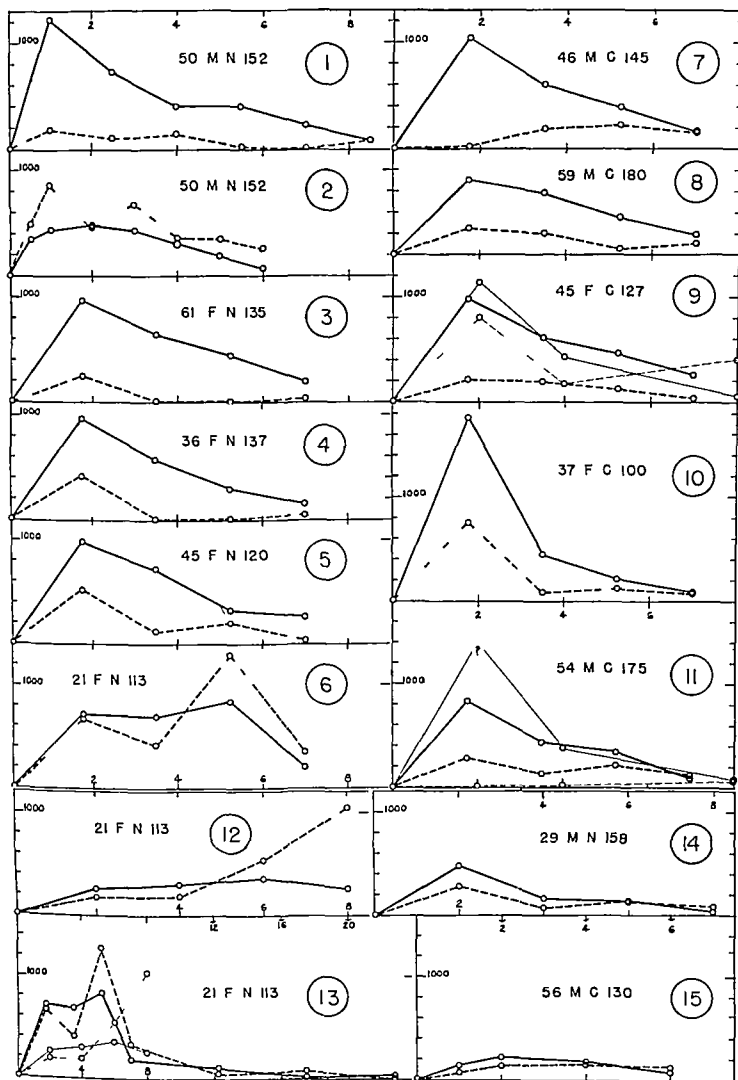

Fig 1—Results of teropterin administration as explained in text. Administration at 0 time.

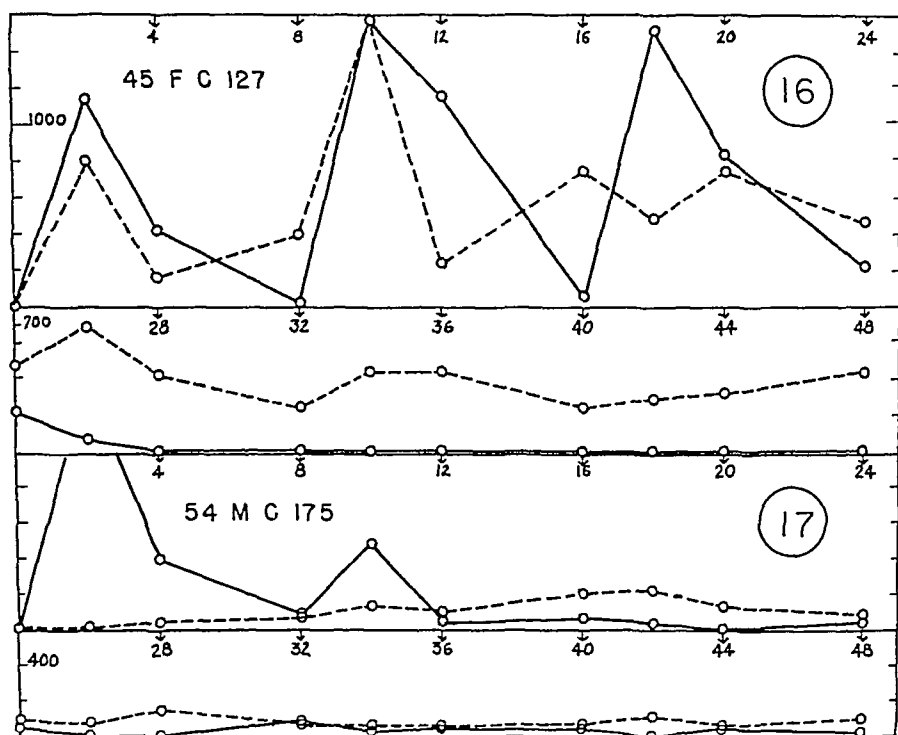

Fig 2—Results of teropterin administration as explained in text. Administrations at 0-8 and 16-hour period

numbers-and-letters code shown above each graph characterizes the subject of the experiment, in the following manner age, sex (M or F), normal (N) or cancerous (C), weight. Thus, 50 M N 152 indicates a normal man of age 50 weighing 152 pounds. The initial concentration for both substances is in all cases shown as zero. The actual normal levels found range from about 5 to 50 tM for folacin. Although as a rule no teropterin was found, a few subjects showed a low initial teropterin activity. Pending further investigation of these observations, the initial levels have been ignored, since in view of their low values, compared with those resulting after administration of Teropterin, no serious error is introduced thereby.

The injections were made intramuscularly in the upper arm. Blood samples were taken from the fingers of the opposite arm. For the 20 mg administration the dry preparation was used, dissolved in 1 cc of saline for the injections. For the 10 mg injections the solution commercially available in vials was used.

Chart 1 shows the results of oral and chart 2 the results of intramuscular administration of 20 mg teropterin in the same subject. Because the latter method yielded much higher teropterin levels, further studies by the oral route so far have not been made. Charts 3 to 6 show the results of 20 mg injections in four additional normal subjects. Charts 7 to 11 show results obtained in five patients with cancer with 20 mg injections. The thin lines in charts 9 and 11

indicate data obtained in later experiments with the same subjects (see charts 16 and 17). Charts 12, 11, and 15 describe the results of 10 mg injections on two normal subjects and one patient with cancer. The experiments described in charts 6 and 12 were done on the same subject. Because of the unusual nature of the delayed response encountered in the experiment of chart 12 (which preceded that of chart 6) blood sampling was extended until twenty-two hours after injection in the experiment of chart 6. Both experiments are plotted together in chart 13.

Charts 16 and 17 describe for two patients with cancer who had been subjects of previous experiments (charts 9 and 11 respectively), the results of an experiment extending over forty-eight hours. During the first twenty-four hours three teropterin injections of 20 mg each were given at eight-hour intervals (zero, eight and sixteen hours).

*Precision*—Prior to further discussion the precision of the data shown in Figs. 1 and 2 should be indicated. A statistical summary of relevant results is given in Table I.

Each entry in this table represents an average obtained from approximately 130 pairs of readings. As stated each blood specimen was analyzed in two concentrations and each of the resulting individual tubes was read after two periods of growth. The resulting "quantity pairs" were always in a 1:2 ratio, and the "hour pairs" consist of readings taken after sixteen and twenty-two hours of growth. During this period the standards showed an average increase in optical density of about 40 per cent. The figures given in Table I represent millimols per cubic centimeter of blood, i.e. the same units as are used in Figs. 1 and 2. Average drift means, for the hour pairs, the

TABLE I

	HOUR PAIRS		QUANTITY PAIRS	
	AV. DIFFERENCE (tM)	AV. DRIFT (tM)	AV. DIFFERENCE (tM)	AV. DRIFT (tM)
<i>L. casei</i>	70	-20	90	+30
<i>Str. faecalis</i>	50	+10	50	+20

net difference between the averages of all twenty-two hour and all sixteen hour readings, and for the quantity pairs, the net difference between the averages resulting from all double and all single levels. Thus the table shows that in the *L. casei* measurements the final figures resulting from the sixteen hour and the twenty-two hour readings differ in the average by 70 tM and the value resulting from the later reading is, in the average, 20 tM lower than the result of the earlier reading. Further, the results of the single and double quantity samples differ in the average by 90 tM and the value resulting from the larger sample is, in the average, 30 tM higher than the result of the smaller sample. Since the folacin values derive directly from the *Str. faecalis* readings while the teropterin values result from the difference between the *L. casei* and the *Str. faecalis* readings their error would in the average be somewhat larger than that of the folacin values. It is concluded from the statistical evidence that

by combining the results of the hour pairs and the quantity pairs into one single average, as has been done in Figs 1 and 2, a reasonable compensation of errors is obtained and that the procedure as used is adequate to reveal the major trends in the blood picture resulting from administration of teropterin.

*Accessory Observations*—A few additional observations made in the course of this work warrant only brief mentioning. Any effects which meals may have on the folacin-teropterin picture of the blood appeared to be negligible in terms of the concentration levels resulting from administration of the pure compound—Quantitative experiments showed that no significant changes result from refrigerator storage of the primary, 1:21, blood dilution—A preliminary study of normal folacin levels in the blood was made, involving six normal persons and six patients with cancer. The following results, in terms of millimols per cubic centimeter of blood, were obtained: 5, 9, 9, 15, 17, and 28, for the normal subjects, and 8, 9, 15, 25, 28, and 35 for the patients with cancer. In the same series the recovery of folacin added to the blood samples was also studied. While the evidence obtained indicates absence of major secondary effects of the blood in the folacin determinations, a more careful study of this angle seems desirable. Our values of 5 to 35 (median 17) mM per cubic centimeter of whole blood, obtained without any treatment except aqueous hemolysis, may be compared with the values obtained by Schweigert and Pearson<sup>9</sup>: 1 to 3 mM on oxalated blood without taka diastase treatment and an average of 86 mM on blood incubated with taka diastase. Denko and co-workers<sup>10</sup> obtained a range of 27 to 120 mM after taka diastase treatment. This comparison suggests that under our conditions some but not all of the bound folacin is set free.

#### DISCUSSION

The dominating effect of the administration of teropterin which emerges from the present observations is the rapid appearance of folacin in the blood stream. The folacin concentration appears to attain its maximum approximately two hours after injection. If the total circulatory distribution volume of the body is assumed to be 21 to 25 per cent of the body weight,<sup>8</sup> the peak values for the sum of teropterin and folacin in the individual subjects average 62 or 74 per cent, respectively, of the theoretical concentration. At the observed peak periods (which may not be the precise actual peak periods) the relative shares of folacin and teropterin are, in the average, 71 and 29 per cent of the total. Six hours after injection an average of 27 per cent of the folacin present at the peak period is left, while the teropterin level at this time has declined to an average of 36 per cent of its value at the peak period. In the calculation of these averages all injection experiments, except those shown in charts 6 and 12, have been used. These will be discussed below.

In terms of the theoretical maximum, based on a distribution volume of 25 per cent of the body weight, the percentage of the injected teropterin which six hours after injection is still accountable in the circulation, as teropterin or folacin, averages 22. On the basis of the urinary excretion

studies of Jukes Franklin Stokstad, and Boehne one may anticipate a six hour folacin excretion of 60 or 70 per cent of the total dose after administration of 20 mg of teropterin. Thus within a margin of 10 or 20 per cent the total dose seems fairly well accounted for between circulation and excretion.

These are average figures. As is evident from inspection of Figs 1 and 2 among the individual subjects the rise and decline of folacin concentration is relatively uniform in character in comparison with the great individual differences encountered among the teropterin patterns. While folacin shows in practically all cases a pattern of steady decline after the initial rise the primary decline following the postinjection peak of teropterin is in many cases followed by a secondary surge. Because of its occurrence in three quarters of the cases considered, the secondary surge is thought to be more than a fortuitous result of combined errors. Furthermore, at the end of the short term experiments (up to eight hours) the teropterin trend is upward in one third of the cases while the folacin trend is always downward. The two forty eight hour studies (charts 16 and 17) show in further confirmation of the different character of the teropterin and folacin patterns that the teropterin to folacin ratio tends to change from a value of less than 1, which is characteristic for the early postinjection periods, to a ratio larger than 1 which is maintained for a considerable period after the last injection.

Because there are equally good reasons for considering folacin an adjuvant of malignant growth as there are for considering teropterin an antagonist, one may theorize that the teropterin to folacin ratio resulting from teropterin administration is more important than the size or frequency of dosage per se. Accordingly the conditions governing establishment and maintenance of a favorable ratio should be studied. The obvious differences in the rates of disappearance of the two compounds suggest a slower rate of excretion of teropterin and/or a process of storage or binding from which teropterin is gradually released.

From a practical point of view it would seem important to know if the response pattern of a subject is determined by stable individual metabolic characteristics or whether the response of the same individual varies substantially and unpredictably from day to day. Among the present data there are a few bearing on this question. Charts 9 and 11 show two cases in which a second analysis was carried out on the same person after an interval of two weeks. In either case the second picture differs substantially from the first. Charts 6 and 12 show two experiments performed on another subject. In this case the dosage levels differed and the interval was six days. The response picture of this person is particularly interesting because of the unusual delay in the attainment of the top levels for both folacin and teropterin but particularly the latter. As chart 13 shows in which the data of charts 6 and 12 are combined this characteristic is in evidence in both experiments despite other differences.

## SUMMARY

Studies, using *L casei* and *Sti faecalis*, of the fate of pteroylglutamic acid in human subjects indicated that two hours after intramuscular injection approximately two-thirds of the dose (20 mg) were present in the circulation. Of this total about two-thirds were present as the mono- and one-third as the triglutamate. Subsequently the concentration of the former seemed to decline more rapidly than that of the latter. Different individuals show considerable variations from the average metabolic pattern.

## ADDENDUM

Upon completion of this article a paper by Schweigert on metabolic observations after administration of pteroylglutamic acid and pteroyltriglutamic acid appeared<sup>11</sup>. Despite differences in approach and methods, the findings of this work are similar to some of our results. In both investigations maximum blood levels were observed approximately two hours after injection, although the route was intramuscular in one case and intravenous in the other. However, in our study the maximum value obtained after two hours (average, about 1,400 tM, average weight of subject, 140 pounds) was more than twice as high as that of Schweigert, although the injected quantity of the triglutamic acid was essentially the same. As noted, our normal folic acid levels are also higher than those recorded by Schweigert. His tentative conclusion "that some of the injected triglutamate was not cleaved for as long as four to eight hours after injection" is fully confirmed by our evidence.

The authors wish to thank Dr Stanley P. Reimann for making available to them the patients who have cooperated in this study. They also wish to thank Lederle Laboratories, Inc., New York, N. Y., and Dr Benjamin W. Carey of that organization for supplying the teropterin.

# A STUDY OF SOME FACTORS INVOLVED IN THE COLORIMETRIC DETERMINATION OF CARONAMIDE

HARVEY SHIELDS COLLINS M S, M D, AND MAXWEIL FINLAND M D  
BOSTON MASS

CARONAMIDE (4' carboxy phenylmethanesulfonamide) inhibits the renal excretion of penicillin and thereby enhances and prolongs the levels of that antibiotic in body fluids<sup>1</sup>. A simple and accurate method for assay of Caronamide is desirable both to facilitate pharmacologic studies and to control dosage. Ziegler and Sprague<sup>2</sup> described a colorimetric method which involves the use of Riney catalyst alloy (powdered Ni Al) to cleave Caronamide and produce para aminobenzoic acid (PABA)

The PABA is then determined by Eckert's modification<sup>3</sup> of Bratton and Marshall's method for sulfanilamide<sup>4</sup>. Ziegler and Sprague presented alternate methods applicable to blood serum both of them depending on the reaction cited. One of these (then method II) involves preliminary deproteinizing while the other (method III) which is run upon serum directly is stated to be less accurate but quicker and hence useful where a high degree of accuracy is not needed. In applying these methods to known amounts of Caronamide certain details were found to affect significantly the amounts recovered. The findings are presented in this paper.

## MATERIALS AND METHODS

*Standard Solutions*—“Primary standards” of PABA and Caronamide were prepared by dissolving 0.001161 mole in 20 ml of 5 per cent NaOH and diluting the solutions up to 1 liter with water. These concentrations were chosen because they are each chemically equivalent to the primary sulfanilamide standard solution used in the Bratton and Marshall method. The primary standards were then diluted 1:10 and 1:20 with 5 per cent NaOH in order to bring the intensity of the color formed in the reaction within the optimal range for the spectrophotometric readings. Such dilutions constituted the secondary or working standards, of which 5.0 ml aliquots contained  $580 \times 10^{-6}$  or  $290 \times 10^{-6}$  meq. These amounts if present in 5.0 ml of filtrate obtained by either method II or III of Ziegler and Sprague would correspond to the presence of 15.9 and 7.9 mg per cent of PABA or 33.8 and 16.9 mg per cent of Caronamide in the serum.

Identical spectrophotometric readings may be expected from equivalent amounts of PABA or Caronamide provided the liberation of PABA from

Received for publication Nov. 20, 1948.

Caronamide is quantitative and no other substances are formed which influence light absorption materially at 540  $m\mu$ , the wave length at which the PABA was determined. The identity with the sulfanilamide standard substantiated the basic path of the reaction and the derived calculations.

*Other Reagents*—These included pooled human serum or citrated plasma, Raney catalyst, n-octyl alcohol, 6N HCl, 90 per cent ethanol, 0.2 per cent sodium nitrite, 2.0 per cent ammonium sulfamate, and 0.1 per cent N-(1-naphthyl)-ethylenediamine dihydrochloride, the last three in aqueous solutions, freshly prepared.

*Apparatus*—Standardized pipettes and 50 and 100 ml volumetric flasks were used. The 0.5 ml samples were measured with Ostwald-Folin pipettes using a set time for drainage. Light absorption was determined with the Coleman Junior Spectrophotometer with the readings made at 540 millimicrons. The maximum absorption actually is close to 547  $m\mu$ , but the difference is of no significance due to the flatness of the absorption curve in this region.

*Procedures*—The recovery of PABA or Caronamide from mixtures containing known amounts was studied under varied conditions, each step in the determinations being carried out in duplicate. A battery of 50 ml volumetric flasks was assembled and into each were pipetted 5.0 ml of one of the secondary standards. To each flask were then added 2 drops of n-octyl alcohol to minimize foaming during the reaction, and, to one-half of the flasks, 0.5 ml of pooled normal human serum was added in order to observe the effects of serum on the determinations. Raney catalyst was then added in varied amounts, namely "0" (for PABA), 0.125, 0.25, 0.5, and 1.0 gram. The catalyst was added through a funnel slowly in order to avoid excessive heating and frothing\*. The flasks then stood at room temperature (22 to 27° C), except for occasional swirling, for two hours, twenty-four hours, or forty-eight hours, or they were heated in a bath of boiling water for one half hour.

After the mixtures were allowed to react for the desired periods they were diluted with water to 50 ml, shaken, and filtered through No. 42 Whatman paper. Subsequent treatment was essentially as described by Ziegler and Sprague: a 5.0 ml aliquot of filtrate was added to each of two matched cuvettes containing 0.5 ml of 6N HCl, then 0.5 ml of 0.2 per cent  $\text{NaNO}_2$  solution was added to one tube of the pair and 0.5 ml of water added to the other, the latter serving as a blank. Diazotization was allowed to proceed for five minutes before adding 0.5 ml of 2 per cent ammonium sulfamate to both tubes and, after three minutes, 0.5 ml of 0.1 per cent N-(1-Naphthyl)-ethylenediamine dihydrochloride was added to each tube. The color was then allowed to develop in a dark place for thirty minutes, after which the spectrophotometric readings were made.

\*Heat is evolved when Raney catalyst is added to the reaction mixture which will be only slightly warmed however if the catalyst is added slowly allowing several moments for the dissipation of heat between increments. Room temperature reactions as used here imply such conditions.

Additional studies were also made to determine the effects of citrate,  $Al^{+++}$ , and  $Ni^{++}$  on the colorimetric determination and also whether PABA might be absorbed on the catalyst

**Calculations**—The amount of color produced was practically identical if equivalent amounts of PABA were run through the procedure with serum but without catalyst—either hot or cold or for a long or short time. Variations from the mean were less than 0.2 per cent, accordingly the average of these determinations was chosen to represent 100 per cent completeness of the reaction. Equivalent amounts of PABA or Caronamide often gave less intense color in the presence of catalyst. In these instances the recovery was calculated from the ratio of the optical densities. Deviations from the mean of duplicate determinations were usually less than 1 per cent for either Caronamide or PABA provided the amount of catalyst was limited to 0.125 or 0.25 gram.

### RESULTS

It was found that the completeness of recovery of either Caronamide or PABA was affected by the duration of reaction, temperature, presence of serum and amount of catalyst. The findings are summarized in Table I and part of them is shown graphically in Fig. 1. The analytical yield from the mixtures studied was superior when the amount of catalyst was limited to 0.125 or 0.25 Gm. this amount was sufficient for the complete cleavage of Caronamide. Serum enhanced the degree of recovery. In one instance in

which starch was substituted for serum, a "protective" effect was similarly observed. Optimum recoveries were obtained at room temperature and with catalytic contact for only two hours.

Certain factors were found to be of little or no importance: (1) the serum itself was not altered in the procedure so as to produce compounds absorbing light in the region  $540 \text{ m}\mu$ , (2) the presence of citrate had no effect, (3) the pH and total acid of the filtrates prior to diazotization were constant regardless of the amount of catalyst, (4)  $\text{Al}^{+++}$  in amounts greater than those which might accrue from the catalyst did not interfere with the colorimetric reaction and  $\text{Ni}^{++}$  also had no effect, (5) caking of the catalyst when used in larger amounts was present variably but could not be correlated specifically with the results, and (6) the volume usurped by the catalyst was small and would in any case cause an error tending to give falsely high recoveries in experiments involving large amounts of catalyst, which is contrary to the observations.

#### OBSERVATIONS ON SERUM OF A PATIENT RECEIVING CARONAMIDE

Method III and method II of Ziegler and Sprague<sup>1</sup> and certain modifications were applied to the serum of a patient who was receiving large doses of Caronamide. Aliquots of a 1:10 dilution of the patient's serum in 5 per cent NaOH were used for a series of analyses and the amount of catalyst was varied

from 0.125 to 1.0 gram. Reactions were carried out at room temperature for two hours, or in a bath of boiling water for one half hour. The resulting reaction mixtures correspond to those in Ziegler and Spiguel's method III, extended with respect to conditions of time, temperature, and amount of catalyst. Another factor, which at first sight might not be expected to affect the determination was also varied: this was the total volume of the 1:10 serum NaOH solution in contact with the catalyst. Studies were made using 5 ml of 5 per cent NaOH (which contained 0.5 ml serum) in a reaction flask of 50 ml volume, as had been done in the preceding section of this paper, and they were also carried out with 10 ml of 5 per cent NaOH (which contained 1.0 ml serum) in a 100 ml flask essentially the volumes recommended by Ziegler and Spiguel.

In addition the serum was deproteinized with 90 per cent alcohol and filtered as in Ziegler and Spiguel's method II. A 5.0 ml aliquot of the alcoholic filtrate, which represented a 1:10 dilution of the serum, was added to 5.0 ml of 5 per cent NaOH in a 50 ml flask and carried through the procedure using various amounts of catalyst either at room temperature or in a bath of boiling water.

**Results**—The Caronamide concentrations obtained with this serum are shown in Table II. It would appear that the results obtained with method II and its modifications compared favorably with those obtained by Method III when the smaller volumes were used. It should be borne in mind, however, that the former values may be as much as 10 per cent in excess of the true values because of the fact that during the filtration some alcohol is lost by evaporation and the solutions become correspondingly more concentrated. A more complete comparison of these methods should include the effect of serum added to the reaction mixture but such a comparison is not possible because of the presence of the alcohol following deproteinization.

Differences were observed in the analytical results when solutions were compared which had similar concentrations but differed in the ratio of volume of solution to the amount of catalyst. Presumably the reaction occurs at the surface of the catalyst and its completion may be determined by a number of

factors involving the surface area in addition to the concentrations in the overlying solution. Boiling serves to stir the mixtures, and it is possible that mixtures of larger volume at room temperature do not adequately mix when only 0.125 Gm. catalyst is added and gas evolution is curtailed.

In these experiments, which employed serum from a patient receiving Caronamide, the results were not so clear-cut as those obtained with the use of standard solutions of the chemicals. This may be due to the presence of metabolic products of Caronamide. The method of Brodie, Levy, and Bernstein,<sup>2</sup> which employs spectrophotometric measurements in the ultraviolet, was not used here. This method is said to determine Caronamide but not its metabolic products and its use may clarify some of the discrepancies.

#### COMMENTS

These studies confirm the usefulness of Raney catalyst alloy as a basis for the determination of Caronamide. It is desired only to emphasize some of the variables which may influence the reaction and the accuracy of the results.

Eckert<sup>3</sup> has observed that PABA is not fully recoverable from mixtures containing a reducing agent. He noted that the loss of PABA could be nearly 15 per cent in one hour when titanous chloride was present as a reducing agent, and that such mixtures, when heated in a bath of boiling water and then allowed to stand a few hours, sometimes yielded very low recoveries. Eckert also considered coprecipitation of PABA with protein to be a possible explanation but concluded that it was probably not significant since variation of the protein concentration over wide ranges had little effect.

It was shown here that, in the presence of Raney catalyst, PABA was recoverable to varying degrees depending on the experimental circumstances. Whether this loss is due to the partial destruction of PABA, or to adsorption on the surface of the catalyst, is not certain. An attempt was made to leach the "lost" PABA from the catalyst, and this was unsuccessful.

The failure to recover Caronamide in full may be due either to its relationship to PABA or to factors peculiar to Caronamide itself. Some of the possibilities which suggest themselves are: the formation of compounds other than PABA upon reduction, or adsorption of Caronamide itself, or competing rates of reduction, destruction and adsorption of the reagents. These details need clarification.

It was shown here that the analytical recovery of PABA or Caronamide from known mixtures of these chemicals can be made better than 90 per cent. It is necessary only to limit the amount of catalyst employed, and to carry out the reaction at room temperature for a short time. The presence of serum enhances the recovery.

The mixtures employed corresponded in the total amounts and concentrations of PABA or Caronamide to those customarily produced during a routine analysis of serum samples from patients according to Ziegler and Sprague's methods. When the method which was found to work best on the synthetic

mixture was applied to the analysis of a serum sample from a patient receiving Caronamide, the comparative results were somewhat less convincing. It appears, however, that the greatest yield was obtained when the reaction was carried out at room temperature and with the smaller amounts of catalyst in the smaller volume.

On the basis of the present findings the following modification of Ziegler and Sprague's method for serum Caronamide determination is suggested.

An accurate 0.5 ml sample of serum is diluted with 5 ml of 5 per cent NaOH (or a 5 ml aliquot of 1:10 serum 5 per cent NaOH solution is used). 2 drops of n-octyl alcohol are added and then 0.125 or 0.25 Gm of the Raney catalyst. After standing two hours at room temperature the mixture is diluted to 50 ml with water, filtered, and conjugated in the usual fashion.

Even small variations from the method as stated affect the determinations. Comparisons of one method with another or with its modifications, should be evaluated with this in mind.

#### SUMMARY

1 The analytical method of Ziegler and Sprague for the colorimetric determination of Caronamide together with modifications has been used for analysis of known solutions of Caronamide and para aminobenzoic acid and for serum from a patient receiving Caronamide.

2 The duration of the reaction, the temperature at which it is carried out, the amount of catalyst and the presence of serum all were found to influence markedly the degree of recovery of Caronamide or para aminobenzoic acid.

3 Recoveries were better in general when the reaction was carried out with serum present at room temperature for two hours and with a smaller amount of catalyst than has hitherto been recommended.

4 A modification of Ziegler and Sprague's method for serum Caronamide determination is suggested on the basis of these findings.

## DIMETHYLETHER OF *d*-TUBOCURARINE IODIDE

EDWARD E. SWANSON, B.S., FRANCIS G. HENDERSON, M.D.,  
AND K. K. CHEN, M.D., PH.D.  
INDIANAPOLIS, IND.

**D**IMETHYLETHER of *d*-tubocurarine iodide is the reaction product of methyl iodide with *d*-tubocurarine in methanol potash. It involves the methylation of the two phenolic hydroxyl groups and an exchange of iodine for chlorine ions. The compound was first prepared by King<sup>1</sup>. Several investigators<sup>2-6</sup> reported that the methylated compound was considerably more active than the natural alkaloid, *d*-tubocurarine. Stoelting, Giat, and Viena<sup>7</sup> found that in man dimethylether of *d*-tubocurarine iodide was highly effective in relaxing voluntary muscles during light anesthesia, and that the required dose was much smaller than that of *d*-tubocurarine. It thus becomes desirable to extend the pharmacologic studies with the methylated alkaloid in order to survey its full action and insure its safety for human use.

The sample of dimethylether of *d*-tubocurarine iodide employed in the present work was air-dried and in the form of trihydrate, melted at 267 to 270° C. with decomposition, and had a specific rotation of  $[\alpha]_D^{25} + 150^\circ$  in aqueous solution. The substance was easily soluble in water. A stock solution of 1:1,000 was prepared, and suitable dilutions were made from it. Wherever possible, the drug was compared with *d*-tubocurarine chloride in the form of pentahydrate.

*1 Neuromuscular Action*—Dimethylether of *d*-tubocurarine was tested for its curarizing effect in the cat and rat. Certain suggestions of procedure were made by Professor G. H. Acheson, University of Cincinnati, based on Van Maanen's publication<sup>8</sup>. Briefly, after the animal was anesthetized with Seconal Sodium (Lilly) (sodium propylmethylcarbonylallyl barbituric acid), the gastrocnemius muscle was exposed, and the tendo calcaneus (Achilles tendon) severed from its insertion. The sciatic nerve was isolated in the thigh and crushed at the site of emergence from the vertebral column. All its branches were cut except those supplying the gastrocnemius muscle. The skin was sewed together to prevent drying.

For recording of contractions, a hook was inserted in the tendo calcaneus and fastened to an isotonic muscle lever. A shielded platinum electrode was placed on the sciatic nerve just distal to the point of crushing. In the rat, a single stimulus of 50 volts from a stimulator (Electrodyne) caused a maximal contraction. This could be repeated every two seconds in each animal for long periods of time. In the cat, it required shocks of 50 volts at a rate of fifty per second for two seconds to produce a maximal, smooth, sustained contraction. This could be repeated every thirty seconds in each cat for intervals of several hours.

After a control period of repeated stimulation, resulting in a series of uniform contractions, the methylated alkaloid was injected intravenously. Observations were continued until recovery occurred. In several animals, the injections were repeated from one to three times. The paralyzing action of the dimethylether is exactly the same as that of *d* tubocurarine, differing only in degree. In six rats, the new alkaloid completely inhibited the contractions in the dose of 24  $\mu$ g per kilogram, reduced the contractions by 76 to 91 per cent in the dose of 16 to 20  $\mu$ g per kilogram, and by 28 to 72 per cent in the dose of 14  $\mu$ g per kilogram. The duration of action of all doses was approximately the same, averaging thirty three minutes. With *d* tubocurarine chloride in six other rats, complete inhibition of contractions occurred with a dose of 112 to 128  $\mu$ g per kilogram and reductions to the extent of 24 to 28 per cent with a dose of 64 to 96  $\mu$ g per kilogram. The average duration of action of these doses was thirty five minutes. No effect was noted in smaller doses. Thus as previously reported,<sup>9</sup> the methylated alkaloid is much more potent than the natural alkaloid.

Six cats receiving the dimethylether in doses ranging from 20 to 24  $\mu$ g per kilogram showed a maximal reduction of 81 per cent in the amplitude of contractions. One of them died from the larger dose in eleven minutes. The average duration of action in the remaining five cats was sixty two minutes. A dose of 10  $\mu$ g per kilogram was ineffective. It was not possible to produce complete inhibition of contractions without causing death. In seven other cats *d* tubocurarine chloride in the dose of 100 to 174  $\mu$ g per kilogram caused on the average, a maximal reduction of contractions by 70 per cent. Two of the cats died of respiratory failure. The average duration of action in the surviving animals was forty three minutes. Fig. 1 contrasts the effects of the two substances. It appears that in the cat the methylated alkaloid is not only more potent than *d* tubocurarine, but also longer acting.

Garcia de Jalon<sup>9</sup> reported that *d* tubocurarine chloride, quantitatively, antagonized the acetylcholine contracture of the frog's rectus abdominis. A similar study was made with dimethylether of *d* tubocurarine in the present work. The rectus muscle of *Rana pipiens* was immersed in a volume of 10 c.c. of aerated Ringer's solution, and its contractions were registered on a kymographic paper. Acetylcholine amounting to 5  $\mu$ g was added to the bath every ten minutes and washed out twice each time at the end of the fifth minute. This resulted in a series of uniform maximal contractions. When various volumes of a 0.0001 molar solution of the methylated alkaloid were placed in the bath one and one half minutes before the scheduled doses of acetylcholine, the amplitude of contractions became reduced. The reduction of acetylcholine contractions was proportional to the amount of the drug superimposed. A comparison was made with *d* tubocurarine also in 0.0001 molar solution on the same muscle preparations by alternating with the dimethylether. In a total of twenty eight parallel observations, dimethylether of *d* tubocurarine was proved to be equally as active as *d* tubocurarine. Apparently, mole for mole *d* tubocurarine and its dimethylether have the same power to inhibit the acetylcholine contraction of the frog's rectus muscle.

Fig 1—Action of dimethylether of *d*-tubocurarine iodide and *d*-tubocurarine chloride on the gastrocnemius sciatic nerve preparation

The tracings were made from a cat weighing 3 647 kilograms anesthetized with Seconal Sodium (35 mg per kilogram) The curves from top to bottom are respiratory movements gastrocnemius contractions carotid blood pressure baseline and time in minutes The sciatic nerve supplying the gastrocnemius muscle was stimulated every thirty seconds (see details in the text) Both alkaloids were injected intravenously The time for full recovery of gastrocnemius contractions following dimethylether of *d*-tubocurarine iodide was 78 minutes and that following *d*-tubocurarine chloride 30 minutes

2 Assay in Rabbits—Like *d*-tubocurarine, the dimethyl-ether produces a head drop of the rabbit by paralysis of the neck muscles The response of this animal is so uniform that it can be used advantageously for assaying purposes, as already advocated by Bennett and co-workers<sup>10</sup> By running a cross over test in a group of thirty rabbits, dimethylether of *d*-tubocurarine iodide, injected intravenously, was found to be almost eight times as active as *d*-tubocurarine chloride, as measured by the median effective dose (ED<sub>50</sub>) The rest period between the days of injection was five days The combined data are shown in Table I Two separate, new lots of the dimethylether were assayed and found to have ED<sub>50</sub>'s of 15 9 ± 1 4 and 16 6 ± 1 2 µg per kilogram, indicating the uniformity of the product

Since a dose of 20 µg of dimethylether of *d*-tubocurarine iodide produced the same response as one of 150 µg of *d*-tubocurarine chloride, per kilogram (see Table I), a special cross-over test was carried out with the same doses in another group of twenty rabbits, for the comparison of onset and duration of

TABLE I COMPARISON OF POTENCY BY INTRAVENOUS INJECTION BETWEEN D TUBOCURARINE AND ITS DIMETHYLETHER BY THE RABBIT CROSS OVER TEST

ALKALOID	DOSE (µG PFR KG )	NO IN HEAD DROP	MEDIAN EFFECTIVE DOSE ± STANDARD ERROR (µG PER KG )
		NO USED	
Dimethylether of <i>d</i> tubo curarine iodide	15 0	4/10	15 8 ± 0 8
	17 5	7/10	
	20 0	9/10	
<i>d</i> Tubocurarine chloride	100 0	2/10	123 0 ± 7 0
	125 0	4/10	
	150 0	9/10	

action. A stop watch was employed. With the methylated alkaloid, 20  $\mu\text{g}$  per kilogram by vein, the average time required for the appearance of head drop was 1.02 minutes, and that for restoration of the head position, 18.25 minutes. With *d* tubocurarine, 150  $\mu\text{g}$  per kilogram intravenously it took an average of 1.75 minutes for the head to drop, and an average of 13 minutes for the animal to raise the head again. It appears evident that in the rabbit the methylated alkaloid has a shorter onset, but a longer duration, of action than *d* tubocurarine.

**3 Decurarization**—Burke and associates<sup>11</sup> recently reported the antidotal action of neostigmine against *d* tubocurarine. In our work, neostigmine methylsulfate was found to have a limited value. For example, the median lethal dose ( $\text{LD}_{50}$ ) of dimethylether of *d* tubocurarine iodide in twenty-five rabbits by vein was  $31.5 \pm 1.1 \mu\text{g}$  per kilogram. When neostigmine methylsulfate in the dose of 50  $\mu\text{g}$  per kilogram was simultaneously injected also by vein the  $\text{LD}_{50}$  of the methylated alkaloid in forty new rabbits was raised to  $53.5 \pm 1.9 \mu\text{g}$  per kilogram. However, when the same dose of neostigmine was given three minutes after the injection of dimethylether of *d* tubocurarine iodide in a third group of fifteen rabbits the  $\text{LD}_{50}$  of the latter became  $38.1 \pm 4.6 \mu\text{g}$  per kilogram. In other words, the antidotal action of neostigmine rapidly diminishes after the methylated alkaloid has been administered.

Further evidence was obtained regarding the narrow efficacy of neostigmine in six etherized dogs. The depression of respiratory amplitude and rate following small doses of dimethylether of *d* tubocurarine iodide, 5 to 10  $\mu\text{g}$  per kilogram, was easily removed by intravenous injection of neostigmine methylsulfate in the dose of 50 to 100  $\mu\text{g}$  per kilogram. The latter however was only capable of delaying death in the etherized dog if the dose of the curari form alkaloid was increased to 20  $\mu\text{g}$  per kilogram or more.

The most effective measure to revive dogs from large and fatal doses of dimethylether of *d* tubocurarine iodide was artificial respiration. It restored their respiration after neostigmine had failed. The work was repeated with equivalent doses of *d* tubocurarine and similar results were obtained.

**4 Synergism With Anesthetics**—Of seven dogs anesthetized with ether three died following intravenous injection of dimethylether of *d* tubocurarine iodide in the dose of 20 to 25  $\mu\text{g}$  per kilogram and four survived a dose of 4 to 8  $\mu\text{g}$  per kilogram. Of five dogs anesthetized with pentobarbital sodium, three died with doses of 60 to 65  $\mu\text{g}$  per kilogram while the remaining two lived with smaller doses. No artificial respiration was applied to any of these animals. When the drug was injected intravenously into four nonanesthetized dogs two on a dose of 75  $\mu\text{g}$  per kilogram lived without artificial respiration and one of the other two on a dose of 100  $\mu\text{g}$  per kilogram lived with artificial respiration. It was also observed in two cats and two rats that a supplementary dose of a barbiturate equal to one tenth of the anesthetic dose given during curarization by the dimethylether was fatal to all of them. These results indicate very clearly that simultaneous administration of the fixed anesthetics and dimethylether of *d* tubocurarine kills animals in smaller doses than when each is injected alone.

In a similar series of eight dogs, four anesthetized with ether and four with pentobarbital sodium, *d*-tubocurarine was lethal in smaller amounts to them than to nonanesthetized animals. Such a synergism is conceivable because when the respiratory center is depressed by the general anesthetics, the muscles of respiration tend to fail more readily with curarizing drugs such as *d*-tubocurarine and its dimethylether.

*5 Action on Respiration, Blood Pressure, Uterus, and Intestines*—In both the anesthetized cat and dog, sublethal doses of dimethylether of *d*-tubocurarine caused a transient decrease of respiration, both in amplitude and rate—the larger the dose, the more the decrease. The decrease in amplitude is clearly illustrated in Fig. 1.

The response of blood pressure was not uniform, as shown in six cats and fourteen dogs. In general, doses of 5 to 10  $\mu\text{g}$  per kilogram were without effect. Occasionally, doses of 20 to 24  $\mu\text{g}$  per kilogram were followed by a rise of blood pressure, particularly in those animals in which the initial pressure was low. A terminal fall of pressure ending in death occurred with lethal doses—some times preceded by a slight rise.

The uterine activity of eight, post partum, anesthetized rabbits was recorded through a pulley. It was observed that dimethylether of *d*-tubocurarine iodide in the dose of 10 to 20  $\mu\text{g}$  per kilogram produced a slight to moderate increase of uterine contractions in four animals, no effect in three, and questionable relaxation in one.

Three observations were made on the skin-covered intestinal loops of two trained dogs, the operative technique of which was described by Wakim and Mason.<sup>12</sup> Intravenous injection of the methylated alkaloid, 10 to 15  $\mu\text{g}$  per kilogram, caused no changes in peristaltic movements.

*6 Toxicity*—The median lethal doses of dimethylether of *d*-tubocurarine were determined by intravenous injection in the mouse, rat, guinea pig, and rabbit—comparisons being made at the same time with *d*-tubocurarine. Death was unquestionably due to respiratory failure, preceded by asphyxial clonic convulsions. As shown in Table II, the methylated alkaloid is less toxic to the mouse, but more toxic to the rat, guinea pig, and rabbit, than *d*-tubocurarine.

TABLE II COMPARISON OF TOXICITY BY INTRAVENOUS INJECTION BETWEEN *D*-TUBOCURARINE AND ITS DIMETHYLETHER

ALKALOID	ANIMAL	NUMBER USED	DOSE RANGE ( $\mu\text{G}$ PER KG)	LD <sub>50</sub> $\pm$ STANDARD ERROR ( $\mu\text{G}$ PER KG)
Dimethylether of <i>d</i> -tubo- curarine iodide	Mouse	60	180.0-330.0	238.0 $\pm$ 13.0
	Rat	28	27.5-50.0	34.5 $\pm$ 1.7
	Guinea pig	22	50.0-62.0	50.4 $\pm$ 2.3
	Rabbit	25	27.5-36.5	31.5 $\pm$ 1.0
<i>d</i> -Tubocurarine chloride	Mouse	50	125.0-200.0	153.0 $\pm$ 5.0
	Rat	24	80.0-125.0	109.0 $\pm$ 5.0
	Guinea pig	15	62.0-80.0	65.7 $\pm$ 3.5
	Rabbit	15	200.0-250.0	221.0 $\pm$ 10.0

A group of eight rabbits were each injected intravenously with an ED<sub>50</sub> for head drop per day for two weeks except Saturday and Sunday. The neck muscles of all animals were paralyzed with complete recovery, showing no development of tolerance. The day following the tenth dose, each rabbit was given a dose of 36.5  $\mu$ g per kilogram. Six out of eight succumbed—further evidence of no tolerance. At necropsy visceral organs including the heart, lungs, liver, spleen, stomach, intestines, kidneys, thymus and adrenal glands, were found normal both grossly and microscopically.

## DISCUSSION

From the foregoing data which agree with those of Collier, Paris and Woolf<sup>6</sup> it is obvious that dimethylether of *d* tubocurarine iodide, like its parent alkaloid, has a blocking effect on the motor end plate of striated muscles of the rat and cat. It reduces the contraction of the frog's abdominal muscle induced by acetylcholine. According to Acheson<sup>13</sup> such a blocking agent "prevents depolarization of acetylcholine by competitive inhibition." Decararization by neostigmine limited in extent is probably due to the protection from hydrolysis of the acetylcholine produced by the motor nerve.

The remarkable feature of this product is that methylation of the two phenolic groups of *d* tubocurarine as shown below results in an increase of potency close to eightfold as measured by the rabbit head drop method—confirming approximately the results of Wintersteiner and Dutcher,<sup>2</sup> and Marsh and co-workers.<sup>4, 5</sup>

This is not due to the change of the molecular size because the ratio between dimethylether of *d* tubocurarine iodide and *d* tubocurarine chloride is 1.2 to 1. In the rabbit and cat, the duration of action of the methylated alkaloid is sub

stantially longer than that of *d*-tubocurarine. The English workers<sup>6</sup> also found the former longer acting in the rabbit than the natural alkaloid. They further observed that, in the rat, the dimethylether was completely excreted in urine, while *d*-tubocurarine was partially eliminated by the renal route.

From a therapeutic point of view, dimethylether of *d*-tubocurarine iodide can adequately replace *d*-tubocurarine chloride in anesthesia, as already reported by Stoelting, Graf, and Vienna.<sup>7</sup> Its longer action in equivalent doses is an advantage. Because of the synergism between anesthetics and curarizing agents, special caution must be exercised in the simultaneous administration of the two classes of drugs. In the treatment of an overdose of dimethylether of *d*-tubocurarine iodide, artificial respiration is far more reliable than neostigmine. This is also true with *d*-tubocurarine.

#### SUMMARY

1 Dimethylether of *d*-tubocurarine iodide inhibits electrically induced contractions of the gastrocnemius muscle of the rat and cat. It reduces the effect of acetylcholine on the frog's rectus muscle.

2 Compared with *d*-tubocurarine chloride, it is close to eight times as potent, the rabbit head-drop method being used. The duration of action is longer with the methylated product in the rabbit and cat than with *d*-tubocurarine.

3 The intravenous toxicity of dimethylether of *d*-tubocurarine iodide by a single injection in the mouse, rat, guinea pig, and rabbit, has been determined and compared with *d*-tubocurarine chloride. Repeated injections do not cause visceral damage.

4 Like *d*-tubocurarine, the dimethylether is synergistic with ether and barbiturates. Artificial respiration is a superior antidote to neostigmine methylsulfate in the treatment of overdosage. This is also true with *d*-tubocurarine.

5 The response of arterial blood pressure in the anesthetized cat or dog to sublethal doses of the dimethylether, injected intravenously, is not uniform—sometimes no change and other times a drop or a rise. A terminal fall of blood pressure occurs after lethal doses, secondary to respiratory failure. In the post-partum rabbit, the methylated alkaloid frequently contracts the uterus in situ. It has no action on the intestines of the trained dog.

The authors are indebted to Miss Marian H. Ellaby, Dr. Paul N. Harris, and Messrs. Clarence E. Powell and Harold M. Worth for their invaluable assistance on various occasions.

# HEREDITARY ANGIONEUROTIC EDEMA, WITH A CASE REPORT

JOHN M. SHELDON, M.D.,\* E. OSKAR SCHREIBER, M.D.,†  
AND ROBERT G. LOVELL, M.D.‡  
ANN ARBOR, MICH.

ANGIONEUROTIC edema is a condition which is alarming to the patient and baffling to the physician. First described by Milton<sup>1</sup> in 1876 as "giant urticaria," the malady usually is called Quincke's edema after Heinrich Quincke,<sup>2</sup> the physician from Kiel. His paper in 1882 on "acute circumscribed edema" has been accepted by posterity.

The majority of patients are consistent in their stubborn failure to respond to the usual methods of treatment, and probably not over 50 per cent of cases are solved in regard to etiology. Cooke<sup>3</sup> states that when the mechanism is discovered, it frequently appears to be related to a current infection in some part of the body, while Cohen<sup>4</sup> suggests that many cases may be traced to drug sensitivity. There remains, however, that large group in whom the cause is a mystery. While the hereditary element in some cases of angioneurotic edema was recognized from the start, a family relationship is not the usual finding.<sup>3</sup> Most attacks occur in individuals who have no family history of edema or accompanying personal allergic manifestations. Lennon<sup>5</sup> nevertheless called attention to ten patients, all women, in whom he found frequently associated histories of asthma, hay fever, or migraine. There is some uncertainty concerning its neurotic origin, but the swelling frequently may be traced to neuropathic families.<sup>6</sup>

We wish to consider the familial type cases which, although a smaller group, seem to have particularly severe symptoms and which are prone to develop glottic edema which often leads to death.<sup>7</sup> The outstanding reported cases of hereditary angioneurotic edema are well summarized by Bulloch,<sup>8</sup> who reviewed the twenty-eight families described in the literature by 1909, and more recently by Cockayne<sup>9</sup> and Gates.<sup>6</sup> For convenience, some of the papers of interest will be reviewed here. Quincke's original work,<sup>2</sup> in which he reported the swelling in a man and two of his children, alerted later clinicians to the hereditary possibility. Osler's paper<sup>10</sup> in 1888 outlined a family in which twenty-two cases of angioneurotic edema progressed in a dominant manner through five generations with only one skip. Ensoi<sup>11</sup> published findings in 1904 from a family in which twenty members were affected in four generations (twelve male members, eight female members). Of these, twelve died from suffocation during an attack. Five years later, Ensoi had collected forty-nine cases (twenty-eight male patients, twenty-one female patients), in six generations in which the heredity was following a dominant pattern, with one skip. Crowder and Crowder<sup>7</sup> in 1917 described twenty-eight cases (fourteen men, fourteen women) which passed

through five generations in a simple strict dominant fashion. There were fifteen deaths in this family due to glottic edema. In 1920 Cameron<sup>1</sup> cited eight cases in three generations in which three members died of suffocation. Dunlap and Lemon<sup>12</sup> in 1929 pointed out eleven cases in which the inheritance was strictly dominant through four generations. Cockayne<sup>9</sup> in 1933 collected the reports of thirty nine families in which there were 257 cases of angioneurotic edema. Of these, twenty four families were described completely enough for him to estimate that the proportion of affected to normal members was 182 involved to 206 uninvolved. The sex ratio of those with the condition was about 15 men to 1 woman.

#### CASE REPORT

The high incidence of death due to glottic edema is fair evidence of therapeutic failure, and the fact that the exact etiology and mechanism of congenital angioneurotic edema are still unknown justifies further case reports. Our case is taken from a family in which the hereditary form of angioneurotic edema was demonstrated in three and possibly six members of the family, and in which the trait was passed through the generations in a regular dominant pattern. The patient was a 24 year old white man of Italian extraction and was first seen in the allergy clinic of the University Hospital on March 6 1946. He gave a history of transient diffuse swellings which had occurred intermittently since the age of 7. The frequency of the attacks varied from once in three weeks to daily occurrence. Each bout lasted from one to three days. Commonly the face, throat, arms and legs were involved but lesions also occasionally appeared on the trunk and genitalia. The swellings were described as frequently following a blow to the affected area, although trauma was not a necessary antecedent. The edematous areas were usually several inches in diameter diffusely indurated and erythematous. Subjectively there was described a sense of tension in the site involved.

In the past there also had been episodes of gaseous abdominal distention and eructation often associated with nausea and vomiting and usually occurring after meals. He had experienced only the usual childhood diseases. There was no history of allergic rhinitis, asthma or eczema. An appendectomy had been performed in March, 1943, presumably following one of the gastrointestinal episodes. The family history was of interest as outlined in Fig. 1.

When the patient was first seen in the allergy clinic he demonstrated diffuse swelling of the left upper arm and of the right knee. The general physical examination revealed a well developed and well nourished young man. Blood pressure was 120/70, and pulse 60. A sebaceous cyst 0.5 by 1.0 cm. was found behind the left ear. The anterior portion of the nasal septum was markedly deviated to the left and moderate lymphoid hyperplasia was noted in the nasopharynx. The heart, lungs, and abdomen were normal.

In April, 1946, study of the blood showed 13.3 Gm. of hemoglobin per 100 cc., 4,700,000 red blood cells per cubic millimeter, and 9,800 white blood cells per cubic millimeter with a differential count of 57 per cent neutrophils, 2 per cent eosinophils, 18 per cent small lymphocytes, 15 per cent large lymphocytes, and 8 per cent monocytes. The hematocrit was 41.0, the mean corpuscular volume was 87, and the sedimentation rate was 8 mm. per hour (Wintrobe method). Examination of the urine showed no abnormality. A routine microflorogram of the chest was read as normal and the blood Kahn serologic reaction for syphilis was negative. A search for foci of infection during this time disclosed no evidence of infection of the mouth, pharynx, gall bladder, nasal accessory sinuses, or genitourinary tract.

The patient was skin tested with 126 allergenic materials. The prick tests were entirely negative in reaction except for a questionable reaction to Endo house dust and caddis fly. On intradermal testing there was read a 4 plus reaction (wheal, pseudopod, and erythematous halo) to Endo house dust, stock house dust, caddis fly, and mugwort. A 3 plus reaction was recorded for orris root, corn smut, quince seed, burweed, marsh elder, wormwood, poplar, willow, pepper, and barley. No correlation could be made between the clinical picture and the skin reactions.

asthma, migraine, eczema, or urticaria. The edema encountered in the first group generally is more severe. It shows a more regular, nonskipping pattern of dominant inheritance and gives least evidence of being associated with a hypersensitive state, except for physical factors, such as heat, cold, and trauma. Gates<sup>6</sup> describes angioneurotic edema as a very irregular dominant condition as viewed by the geneticist. The inheritance, he feels, is not recessive, but rather is incompletely or irregularly dominant.<sup>14</sup> Cockayne<sup>9</sup> suggests that the basic cause of the edema is protein hypersensitivity, particularly in patients with associated asthma and urticaria. Fineman<sup>12</sup> looks upon the condition as nonallergic and proposes that it is caused by physical and emotional exciting agents. In our case we were unable to point to any allergic basis for precipitation of the attacks of edema. The findings in the family we are reporting lead us to believe that we are dealing with an example of a dominantly inherited classical form of Quincke's edema. We previously instructed the two members (the patient and his sister, *II-9* and *II-4*) that the disorder would be expected in half of their respective offspring. Onset of bouts of edema may occur at any age, but usually appear before the age of 20. In this family, ages at first attack were 2, 10, and 7 years, respectively (*II-1*, *II-4*, *II-9*). Edema of the gastrointestinal tract is reported commonly and evidently occurred in the patient (*II-9*), his sister (*II-4*), and his father (*I-1*). As to whether the father never experienced subcutaneous swellings, or whether these occurred in early life and later were replaced by abdominal attacks, we can only speculate, but both such clinical courses have been described in certain affected members of reported families. When encountered without previous history of external swellings, a localized angioneurotic edema of the abdominal viscera has been mistaken frequently for appendicitis, cholecystitis, and other acute illnesses, and it is possible that such may have been the explanation for *II-2*'s operation. However, evidence for involvement of angioneurotic edema in this child and his sister (*II-3*) must be regarded as questionable.

Brain and meningeal symptoms have been described in cases of angioneurotic edema<sup>16</sup> and this complication has been suspected of causing death in one member of Halsted's<sup>17</sup> family, so there is basis for wondering if the cephalopathy described in our patient's father (*I-1*) might not have been caused by cerebral edema. Epistaxis was a frequent finding in Ensor's<sup>11</sup> family. But the most striking features of classical Quincke's disease are as we have said, the severity of symptoms and the high proportion of deaths which result from edema of the larynx and glottis. In the family we studied, *II-1* undoubtedly succumbed in this way, and it seems quite likely that *II-3* did likewise. Proved cases of laryngeal angioneurotic edema in infants are recorded,<sup>18, 19</sup> and many suspicious cases are recounted in other published families. Cotterman<sup>20</sup> has pointed out that of the 170 cases of Quincke's disease contained in the twenty-eight families reviewed by Bulloch, fifty-three deaths are recorded, of which thirty-six or 68 per cent were attributed to edema of the larynx. The age at the time of suffocation is specified in twenty-four of these cases and the mean age is  $34 \pm 3$  years, with standard deviation  $18 \pm 4$  years. With such an early average

age of death, it seems quite probable that some selection is operative against the gene for Quincke's disease and that the condition should tend to disappear. But the incidence of the disease seems to be holding steady and therefore the supply of genes for Quincke's disease must be replenished by the process of mutation. Consequently Cotterman advances the thought provoking question which was first suggested by Cockayne<sup>9</sup> which entertains the theory that a considerable proportion of the reported sporadic cases of angioneurotic edema may be the recipients of mutations and thus may constitute the potential starting members of new family lines of this disease.

An interesting additional discovery in our patient's family was another rare hereditary trait namely blood group A,B. The study of this condition is continuing.

#### SUMMARY

Angioneurotic edema or Quincke's edema usually is not hereditary but there is a small group in which the condition is inherited and in which the trait is passed from one generation to the next in a dominant manner. This group experiences remarkably severe symptoms and death is not unusual during an attack. A case is presented from a family in which the edema definitely affected three and possibly three additional members of two generations. Treatment with histamine may have afforded some protection as long as it was administered and Benadryl given intravenously as soon as symptoms began may have lessened the severity of attacks but no measure was adequate in protecting the patient from a fatal attack of edema. At present we can only speculate about the apparently inherited flaw which permits the outpouring of edema fluid with no obvious provocation.

The authors wish to acknowledge the extensive cooperation of Dr C. A. Alexander of Kalamazoo for the follow up on the patient's history and of Dr Charles W. Cotterman of the University of Michigan Heredity Clinic for the genetics investigation of the family involved and for his many helpful suggestions.

# FACTORS INFLUENCING THE PRODUCTION OF ANAPHYLAXIS IN GUINIA PIGS WITH WEAKLY ANTIGENIC PROTEIN HYDROLYSATES

L W ROTH PH D R K RICHARDS M D AND I M SHEPPERD, B S  
NORTH CHICAGO, ILL

**I**NTRODUCTION of the concept of intravenous protein alimentation, during conditions in which the oral route is temporarily impractical or impossible, raised many questions in the field of applied and clinical physiology. One important problem was the question of potential antigenicity of partially hydrolyzed proteins. With the possibility of repeated and intermittent use of such materials in human beings, the elimination of all antigenic characteristics becomes important if not imperative because of the unpredictable dangers of sensitization and anaphylaxis.

Evidence is available in the literature<sup>1, 2</sup> to indicate that relatively small peptide aggregates may possess some degree of antigenicity. In the acid hydrolysis of proteins the occurrence of such molecular size is inevitable at some stage of the breakdown. In the case of fibrin, which itself is antigenic,<sup>3, 4, 5</sup> the intermediate degradation products may be only weakly antigenic. The antigens if present can be specific entities and may not produce antibodies that cross react with the parent material or vice versa. Such was observed in preliminary experiments attempting to test for the presence of antigens by employing an alkaline solution of fibrin either as the sensitizing or shocking agent and using an acid partial hydrolysate of fibrin as the corresponding material for shocking or sensitizing respectively. No anaphylactic symptoms were demonstrable nor were positive results obtained in similar experiments using blood plasma and fibrin hydrolysate reciprocally. These results are similar to those obtained by Lindsteiner with digested egg proteins,<sup>6, 7</sup> but differ from experiments with some enzymatic hydrolysates of sheep serum or casein in which the parent material or even skim milk may better be used for shocking animals in instances of anaphylactic sensitivity induced by an antigenic hydrolysate. The failure of fibrin to behave similarly made it necessary to use the hydrolysate itself when the latter was suspected of being antigenic.

Since several techniques currently used in testing for antigenicity of protein hydrolysates uniformly yielded negative or very unsatisfactory results in the production of an anaphylactic state in guinea pigs, further experiments were conducted with a view to testing various procedures when a hydrolysate of known antigenicity was employed. In the experiments to be described, (unless otherwise specified) all were conducted with the same material, an acid partial hydrolysate (5 per cent solution) of beef fibrin containing 30 per cent free amino acid nitrogen and all shocking doses were administered via the dorsal penile vein.

From the Department of Pharmacology, Abbott Laboratories  
Received for publication Jan 10 1949

The following methods were carried out (a) One intraperitoneal injection of the 5 per cent solution containing the equivalent of 500 mg (dry weight) of material was given to each of twelve animals. Three weeks later, the injection of a challenging dose containing 100 mg of the same material failed to produce anaphylactic symptoms in any of the animals (See Table I). The unsatisfactory results attained by means of this simple but common procedure illustrate the difficulties involved in demonstrating antigenicity.

(b) Three intraperitoneal injections, each containing 200 to 250 mg of material, were given at two day intervals to eight animals. No anaphylactic results were obtained when the animals were challenged after three weeks (Table I). An occasional, nonfatal reaction was observed, however, after four or six weeks.

(c) Three intraperitoneal injections, each containing 250 mg of material, were given at five-day intervals to nineteen animals. After four weeks, anaphylactic reactions were demonstrable in only 11 per cent of the animals challenged with 250 to 500 mg of material (Table I).

(d) Ultimately, a procedure was devised which produced satisfactory sensitization in a much higher percentage of the animals. Doses of 4 to 5 cc of the solution (200 to 250 mg of material) were injected intraperitoneally into healthy male guinea pigs (250 to 400 grams) six times during a two-week period. The animals then were not used for at least thirty to thirty-one days

For shocking each animal was challenged with doses of 3 to 12 cc (150 to 600 mg) of the sensitizing material and it was found necessary to inject the test dose intravenously at a rate not less than 1 to 3 cc per minute. Injections of these volumes may be given readily via the dorsal penile vein as this route permits the solution to be introduced at any desired rate, avoiding anesthesia, surgery, or the hazard of cardiac damage. (In some exploratory experiments the duration of infusion via the penile vein was extended to thirty minutes or more, with volumes up to 25 cc.)

As mentioned when the material was given at rates of 1 to 3 cc or more per minute, fatal anaphylaxis resulted in some animals, and various degrees of shock symptoms were exhibited in nonfatal cases (Table I). If, however, the same amount of material was infused at 0.25 to 0.5 cc per minute the incidence of any symptoms was extremely low and fatalities never occurred.

It should be noted that although volumes ranging from 3 to 12 cc or more were given to different animals the onset of anaphylaxis as seen in retrospect invariably occurred with 3 cc or less if the injection rate remained constant. The larger amounts were given only to assure ourselves that the absence of anaphylactic symptoms was not due to insufficient material. Therefore in later experiments 3 cc of solution were uniformly employed.

When animals were tested after three to four weeks rather than after a full month, the percentage of reactions was diminished and the severity of those observed was less. From one group of twenty guinea pigs sensitized as usual, three animals were taken at random after twenty eight days of incubation and given a challenging dose of the antigenic hydrolysate. Their reactions ranged from negative to only minimal symptoms. Two others tested three days later died of anaphylactic shock and in subsequent tests two thirds of the animals exhibited moderate to severe reactions. This noticeable change in apparent sensitivity in three days might be coincidental. However, it seemed expedient to set an arbitrary thirty to thirty one day minimum incubation period, and subsequent results seemed to justify waiting the few additional days.

Some variations in sensitivity were encountered in different groups given the same antigenic material and certain animals (less than 20 per cent on the average) were relatively resistant to sensitization under any conditions, a variability noted repeatedly but commonly not so distinctly as with our antigenic material. For the most part however sensitivity could be established by the procedure already detailed and it could be maintained or even increased by the intraperitoneal administration of a booster dose. The same amount as the single dose described was given to any animals surviving a test procedure or remaining unused for a period of time. These animals could be used again for testing after eight to fourteen days. Some have been reused in this manner as often as twenty times with no significant decrease in sensitivity. Adequate sensitivity of a group was established each time by selecting representatives at random and challenging them with minimal amounts of material (0.5 to 1.5 cc) sufficient to elicit anaphylactic symptoms without causing death, so that these pilot individuals might be saved for later use.

Table I summarizes the results of the various sensitizing schedules attempted. It will be noted that most of them employ a total of 500 to 750 mg of material, whereas the successful technique just described exceeds 1 Gm total solids. The alum precipitation method (to be discussed later) also showed as successful results only when a similarly larger amount of total solids was used.

When guinea pigs were sensitized with solutions which had been hydrolyzed for longer times, the antigenic potency was progressively reduced, until a point was reached where sensitivity no longer could be demonstrated (see Table II). This had been shown earlier in dogs by Sayhun and co-workers<sup>8</sup> with an acid hydrolysate of casein. With the fibrin hydrolysate, more than half of the nitrogen was in the free amino acid form at this point, and the peptides still remaining apparently were essentially devoid of antigenic characteristics.

If, however, other materials of approximately the same degree of hydrolysis, which by themselves were not found to be capable of sensitizing animals, were then used as the challenging dose for animals sensitized with the known antigenic material mentioned, anaphylactic reactions were occasionally encountered. This might imply that the challenging material may contain substances which fail to produce antibodies, but which are capable of reacting with the antibodies of adequately sensitized animals. This interpretation is in accord with the findings of Landsteiner on the demonstration of anaphylaxis by resorcinol diazo dyes that are by themselves not able to induce sensitization.<sup>9</sup> On the other hand, it is possible that if the animals were given the material a sufficient number of times, antibodies might be formed, although such a result could not be demonstrated with as many as nine injections of such material.

With other similar materials it was sometimes possible to find no anaphylactic symptoms when the challenging dose of 3 to 6 c.c. was given at 2 to 3 c.c. per minute, yet when other animals of the same group received the same amount of material at 6 c.c. per minute, anaphylactic reactions were occasionally elicited.

Partial despeciation of the parent material was demonstrated repeatedly, as might be expected from such a hydrolytic procedure. Animals sensitized to a partial hydrolysate of beef fibrin would show anaphylactic reactions, ranging to fatal, when challenged with a partial hydrolysate of hog fibrin, and vice versa. However, some degree of specificity still remained, as was shown by sensitizing groups of animals with a mixture of beef and hog fibrin hydrolysates, each known to be antigenic. Occasionally, after challenging such animals with one of the sensitizing agents, and allowing for the disappearance of shock symptoms, the injection of the other agent would elicit a second anaphylactic response, whereas animals receiving a second injection of the original agent showed no further symptoms. We interpreted the latter observation as sufficient evidence to rule out incomplete reactions.

In all the experiments described, results were checked by the injection of the material under parallel conditions into nonsensitized animals. In no instance were any symptoms noted which in any way resembled the anaphylactic responses obtained in sensitized animals. Conversely, injection of nonantigenic

material into animals known to be sensitized to the antigenic hydrolysate likewise elicited no anaphylactic effects. In fact, with either procedure usually nothing more was noted than would occur with the injection of the same volume of physiologic saline given at a similar rate.

More recently, the technique of alum precipitation to enhance antigenicity has been tried. To each 100 c.c. of antigenic hydrolysate (a 5 per cent solution) 30 c.c. of 10 per cent aqueous potassium alum were added and sufficient NaOH was used to adjust the pH to 7.0. After thirty minutes with repeated agitation, the material was centrifuged. The supernatant solution was either employed to resuspend the precipitate or was discarded and more of the original hydrolysate solution was used instead. Earlier groups received the precipitate intraperitoneally (with or without supernatant fluid) from material equivalent to 750 Gm. solids of parent hydrolysate. Later groups received an amount equivalent to 1 Gm. or more. Results have varied with some groups showing a high proportion of sensitive animals while other groups had a low incidence of sensitization. As can be seen in Table I c, there appears to be some correlation with the amount of sensitizing material.

Despite the reasonably comparable incidence of anaphylactic reactions in the alum precipitate sensitized animals, the resulting palpable masses of unabsorbed material that remained in the abdominal cavities of the guinea pigs rendered this method less desirable for our purposes, particularly inasmuch as we wished to use the animals repeatedly over long periods of time. In a few animals multiple adhesions and other evidence of irritation were noted. In one there appeared to be a sterile necrosis. On the other hand, several hundred animals have received the six dose injections of unaltered hydrolysate and none have been observed to develop pathologic changes in the abdomen.

Separate tests on the precipitate (redissolved) and on the supernatant solution from the alum precipitate method on other sensitized animals revealed that antigenic properties were present in both.

It is probable that the antigen of such protein hydrolysates is not a single entity but its detection or isolation has not yet been accomplished. Saturated trichloroacetic acid precipitation tests are not sufficiently sensitive, as antigenicity exists when no precipitate is present. Ten per cent picric acid precipitation also fails to differentiate, as an antigenic solution may give either a positive or negative test for precipitate. Saturation with ammonium sulfate still fails to provide complete correlation since a material may show haze or precipitation by this test and yet not be demonstrably antigenic. However in our limited experience in no case was it possible to demonstrate antigenicity when haze or precipitation was absent.

#### DISCUSSION

Many other individual experiments too numerous and scattered to describe here serve to corroborate further the observations reported. It is apparent that three factors, each necessary but not sufficient may be interdependent to determine the degree of sensitivity demonstrable with weakly antigenic protein

hydrolysates The incubation period was the first to be suspected, and extending it beyond four weeks brought about some increase in the incidence of shock symptoms The three-week period usually used with strong antigens was uniformly insufficient

The number of sensitizing injections is apparently important if the total mass of the antigenic moiety is a requisite in evoking antibody production From our results it is not possible to state definitely whether the antigenic hydrolysates contain a small amount of a potent antigen or a larger amount of a weak antigen However, in the experiments with the alum-precipitated material showing antigenicity both in the precipitate and supernatant solution, the impression would be that we are dealing possibly with multiple antigenic materials, all of which are weak

The speed of injection, when varied over a tenfold range, can be shown to have a significant influence on anaphylactic symptoms, whether the antigen be weak or strong, provided that the proper range is chosen This is probably a matter of controlling the rate of antigen-antibody combination with its release of histamine and/or other substances responsible for the anaphylactic symptoms When all factors are operating at their optimal level, sensitivity may be demonstrated more consistently, whereas a deficiency of any one of the factors will materially diminish the incidence of shock reactions

The evidence accumulated also emphasizes that the use of the converse procedure—namely, sensitizing with a hydrolysate to be tested for antigenicity and shocking with the known antigenic lot of digest—presents two possible shortcomings The first is that some lots tried, as mentioned earlier, failed to sensitize animals and yet would produce shock in animals sensitized with the antigenic hydrolysate This means that antigenic potentialities might be missed by this method The second disadvantage is merely one of time, since the presence or absence of antigenic characteristics would not be known for at least six weeks, while the use of the technique described herein at length affords an immediate answer when a stock of animals sensitized to the antigenic product is continuously available

#### SUMMARY

With weakly antigenic protein hydrolysates, at least three factors are important to insure satisfactory demonstration of anaphylaxis in guinea pigs These are a larger number of sensitizing injections, providing a greater total amount of material, a prolonged incubation period of at least one month, and a rate of intravenous injection of about 2 cc per minute

Antigenic substances produced from fibrin by acid hydrolysis may be partially despeciated and may not cross-react with the parent material They also are destroyed ultimately by further hydrolysis, before the breakdown into amino acids is complete

Related materials from different species may have both common antigens and at the same time specific antigens

The authors wish to acknowledge with appreciation the suggestions and constructive criticism received from Dr M W Chase during the course of these experiments

## STUDIES OF AGGLUTINATION AND INHIBITION IN TWO LEWIS ANTIBODIES

O J BRENDEMOEN, M D  
OSLO, NORWAY

LEWIS antibodies originally were described by Mourant,<sup>1</sup> who found two O serums containing an identical antibody which agglutinated a previously unknown blood type. Both serums originated from women having borne children suspected of having erythroblastosis fetalis. In one case serum from the mother agglutinated cells from the child, whereas in the other case no agglutination occurred. In one case the woman's serum agglutinated cells from the husband, M<sub>1</sub> Lewis, thus the name. In a series of ninety-six O blood specimens the Lewis agglutination was independent of the Rh, MN, P, Lutheran, and Kell types. Of the ninety-six O blood specimens, twenty-four were Lewis positive, one doubtful positive. A study of fifteen families showed that the Lewis type probably was a dominant hereditary quality, though this was not statistically proved.

On the other hand Andriesen<sup>2</sup> has studied the Lewis agglutination in 500 adults of which 21 per cent were Lewis positive. Testing of children showed that about 70 per cent of the infants were Lewis positive before the age of 6 months. The incidence decreased with age to about 21 per cent as found in adults, and at the age of 1 year was about the same as in adults. According to Andriesen the Lewis types of mothers and their children strongly indicated that the 21 per cent Lewis-positive adults represented homozygotes of a possible Lewis-positive gene ( $L/L'$ ), furthermore that the about 70 per cent Lewis-positive infants represented homozygotes and heterozygotes ( $L/L' + L'/l'$ ), and that  $l'$  would become dominant to  $L'$  with increasing age.

### MATERIALS

The present investigations are mainly based upon two serums, one of which (An) by Andriesen has been characterized as identical with his own anti-Lewis serum, but weaker, and by Mourant as a potent Lewis antibody. The serum An originates from an A<sub>1</sub>MN 11 patient, a bipara whose children were healthy at birth. The cells of the actual child, type A MN 11, Coombs negative, were not agglutinated by serum from the mother by any of the methods mentioned below.

The other serum, Ness, originates from an A<sub>1</sub>M R<sub>1</sub>R<sub>2</sub> patient, a bipara whose children were healthy at birth. The husband was O MN R<sub>1</sub>R<sub>2</sub>. His cells behaved in serum Ness and serum An as a slightly Lewis positive.

Serum An had an anti-B titer of 2048; cold agglutinin titer of 2, Lewis antibody titer of 2 in saline medium, 8 in serum medium.

Serum Ness had an anti-B titer of 1024, cold agglutinin titer of 4, Lewis antibody titer of 4 in saline medium, 8 in serum medium.

From the State Institute of Public Health Serodiagnostics Department Chief Otto Hartmann

Received for publication Sept 15 1948

Both anti B titers were higher than the average the cold agglutinin titers were average values in our hands

The Lewis antibody titers have been checked microscopically by Rh technique against a 2 per cent suspension of Lewis positive cells in saline and in serum medium respectively (serum from a Lewis negative person) The agglutination was only slightly stronger at room temperature than at 37° C Both antibodies gave negative reactions by Coombs' test Poor and unreliable reactions were obtained when albumin medium was used

*Relationship of the Two Serums to O and H Antibodies*—When the two serums were tested at +5° C a panagglutination was seen due to the cold agglutinins It could not be demonstrated that this agglutination was stronger in A<sub>2</sub> and O blood specimens compared with A<sub>1</sub> blood specimens Neither after absorption of the serums with A<sub>1</sub>B cells could any cold agglutination against A and O cells be demonstrated

After Morgan<sup>3</sup> the formerly named anti O reagents may be subdivided into two groups

1 The group of H antibodies, consisting of the heteroantibodies Shugella goat immune and cattle anti O reagents and an unknown proportion of human anti O reagents The H antibodies are strongly active on O A and AB cells, weaker and unreliably active on B A<sub>1</sub> and A<sub>1</sub>B cells These antibodies are easily inhibited in human saliva independent of ABO genotype

2 The group of O antibodies of human origin, which agglutinate a product of the O gene in the cells These antibodies are not inhibited by saliva

Four anti O reagents found in our laboratory in serums from pregnant women have according to this very markedly different behaviour in saliva inhibition tests been subdivided into two most probably H antibodies and two most probably O antibodies These antibodies agglutinate cells from Ness in the following manner

Two O antibodies nonabsorbed	+
Two O antibodies absorbed with A <sub>1</sub> B cells	+
Two H antibodies nonabsorbed	(+)
Two H antibodies absorbed with A <sub>1</sub> B cells	-

Since cells from Ness are agglutinated by O and H antibodies such anti bodies cannot be present in her serum

Cells from An were not available for these tests

A<sub>1</sub>A<sub>2</sub> subdivision in the material below is performed with a potent anti A<sub>1</sub>, produced from an anti A serum by absorption with A cells The Rh types are tested with Rh antibodies not containing Lewis antibodies

#### METHODS

Besides the definitely positive reactions doubtful reactions always were encountered in serum An at 37° C and at room temperature by all methods employed (cells suspended in serum, citrated plasma saline, dextrose saline) Because of this fact, the following technique was used in a more extensive series Cells from O and A clots (blood donors) about 24 hours old were suspended to about 1 per cent in saline, centrifuged, and resuspended to about

1 per cent in saline. One drop of the cell suspension and 1 drop of serum An (anti-B not absorbed) were mixed in a Rh tube, incubated for two hours at 37° C, and read microscopically on slides. By this technique doubtful reactions generally were avoided.

In a series of 285 nonrelated blood donors whose A<sub>1</sub>, A<sub>2</sub>, O, and sex distribution were within normal limits, 21.75 per cent Lewis positive were found by this technique, independent of MN and Rh type, and in a smaller group also independent of P type. The agglutination, however, was not completely independent of A<sub>1</sub>, A<sub>2</sub>, and O type, as shown in Table I.

TABLE I

		NUMBER INVESTIGATED
A <sub>2</sub>	27.7% Lewis positive	36
A <sub>1</sub>	22.9% Lewis positive	109
O	19.3% Lewis positive	140
Total	21.75% Lewis positive	285

However, other techniques gave a higher frequency of Lewis positives. A series was tested at 37° C in parallel with two different concentrations of cells: 1 per cent washed suspension and 5 per cent unwashed suspension of cells. One drop of each concentration was incubated for two hours with 1 drop serum An and then read microscopically, any trace of agglutination being recorded as positive. The results obtained are shown in Table II.

TABLE II

NUMBER	1% SUSPENSION	5% SUSPENSION	
10	+	+	Termed strongly Lewis positive
8	-	(+)	Termed slightly Lewis positive
29	-	-	Termed Lewis negative

The test gave the same results in cells from fresh citrated blood as in cells from clotted blood stored for twenty-four hours. The same technique used at room temperature on the same series added some doubtful agglutinations in the 5 per cent suspension, but not in the 1 per cent washed suspension. In slightly Lewis-positive blood specimens also Coombs' test was negative. Absorption series consisting of a total of forty samples gave the results shown in Table III.

TABLE III

	SERUM AN ABSORBED AT ROOM TEMPERATURE WITH 1/5 VOL CELLS OF TYPE		
	STRONGLY LEWIS POSITIVE	SLIGHTLY LEWIS POSITIVE	LEWIS NEGATIVE
Absorbed serum tested at room temperature against 5% sus- pension of			
Strongly Lewis positive cells	-	+	+
Slightly Lewis positive cells	-	-	(+)

Even serums absorbed with equal volume of slightly Lewis-positive cells agglutinated strongly Lewis-positive cells. However, absorption tests with 1/5 volume of cells were not quite reliable as some of the strongly Lewis-positive blood specimens did not cause a complete absorption. The serums absorbed may

agglutinate slightly when tested against other strongly Lewis positive blood specimens

*Action on Cells From the Newborn (Blood Specimens From Umbilical Cords)*—Our anti Lewis serums have been found to agglutinate these blood specimens, but very slightly compared with blood from adults which is confirmed by Andresen<sup>4</sup>

For a closer examination of serum An inhibition tests in saliva were attempted. However serum An obviously readily deteriorated in saline. Serum Ness was stable in saline. Serum An and serum Ness behaved in the same way at 37° C, but not when a 5 per cent suspension of cells was used at room temperature. Serum Ness agglutinated weakly more samples than serum An at room temperature.

*Inhibition Technique With Serum Ness*—Samples of saliva rapidly collected, were boiled for twenty five minutes, centrifugated and some of them stored frozen for some days. The saliva was diluted with saline (volumes of 0.2/1.8 c.c.) as shown in the following series:

1     $\frac{1}{10}$      $\frac{1}{100}$      $\frac{1}{1000}$      $\frac{1}{10000}$

One drop of each of these dilutions was mixed with 3 drops of serum Ness (anti B not absorbed) in Rh tubes and incubated for ten minutes at room temperature. Two drops of each of these mixtures were then transferred to slides and mixed with 1 drop of a 1 per cent suspension of strongly Lewis positive cells in saline. The slides were placed in a moist chamber at room temperature and read after thirty and sixty minutes. The following were used as controls: a 3 drops serum/1 drop saline mixture and a 3 drops serum/1 drop saliva mixture (undiluted saliva from female Lewis negative Lewis antibody producers). The number of positive reactions was not larger after sixty minutes than after thirty minutes.

TABLE IV. AGGLUTINATION INHIBITION TESTS IN SERUM NESS WITH SALIVA FROM 49 PERSONS WHOSE CELLS ARE CLASSIFIED BY MEANS OF SERUM NESS AS STRONGLY LEWIS POSITIVE (LEWIS +, 14 INDIVIDUALS), SLIGHTLY LEWIS POSITIVE (LEWIS +), 3 INDIVIDUALS) AND LEWIS NEGATIVE (22 INDIVIDUALS)

SALIVA DILUTIONS		SALIVA FROM		
NO INHIBITION		LEWIS + PERSONS	LEWIS (+) PERSONS	LEWIS NEG PERSONS
1 10 000	1 1 000	3		
1 1 000	1 100	9		3
1 100	1 10	2	2	11
1 10	Undiluted		1	10
No inhibition in undiluted saliva				8

Three Lewis antibody producers

Lewis group specific inhibition in serums was investigated in fifty blood donors. The saliva inhibition had been studied in most of these cases. One drop of the serum to be investigated was mixed with 1 drop of serum Ness in an Rh tube, incubated for ten to fifteen minutes at room temperature, transferred to slides, and tested as in the saliva inhibition test. By this method the agglutination was inhibited only in serums from strongly Lewis positive individuals.

The serum inhibition was then titrated in the following manner To a series containing increasing amounts of serum Ness in Rh tubes, 1 drop, 2 drops, 3 drops and so on, was added 1 drop of the serum to be investigated The same technique as outlined was used otherwise Agglutination (no inhibition) varied from one case to another from 3 to 7 drops of serum Ness As an average, inhibition occurred by 3 volumes of antibody being added to 1 volume of serum, whereas 4 volumes of antibody to 1 volume of serum caused agglutination There was no marked parallelism between saliva and serum inhibition in the same individuals

*Relation to the B Group*—After absorption of anti-B in serum Ness with B Lewis-negative cells, three of sixteen B blood specimens were found Lewis positive, thirteen Lewis negative

*Relation Between Cold Agglutination and Lewis Type*—Serums obtained from ten donors containing cold agglutinins of medium strength were tested against panels of fifteen blood specimens of known Lewis type by the following technique 1 drop of a 3 per cent suspension of cells was mixed with 2 drops of serum on slides and incubated at +5° C for fifteen to thirty minutes No relationship could be traced between the Lewis type and the intensity of the cold agglutination

#### COMMENTS

It is evident that the saliva of most persons termed Lewis negative contains Lewis-positive substances, which inhibit serum Ness The simplest explanation to this may be as follows Estimated by serum Ness, the erythrocytes of most individuals termed Lewis negative contain too small amounts of Lewis-positive substances to be traced by serum Ness On the other hand, sufficient amounts of Lewis-positive substances will be present in the secretions of the same individuals The phenomenon that inhibiting Lewis-positive substances can be traced in saline used for washing of strongly Lewis-positive cells, but not in saline used for washing of Lewis-negative cells from Lewis-positive secretors, can be explained in the same way

The deviation in A<sub>2</sub> A<sub>1</sub> O distribution as to the incidence of strongly Lewis-positive individuals is statistically nonsignificant

#### SUMMARY

Two Lewis antibodies are studied Among 285 individuals, 21.75 per cent were found Lewis positive Inhibition phenomena in serums and saliva from about fifty individuals are examined In serum inhibition tests, only Lewis-positive individuals presented a Lewis group specific inhibition in their serums In saliva inhibition tests, forty-one of forty-nine saliva specimens presented a Lewis group specific inhibition

## THE OCCURRENCE OF ALSO POSITIVE TRICHINA PRECIPITIN TESTS IN INFECTIOUS MONONUCLEOSIS

FRANK A. BASSEN, M.D., ANNIS F. THOMSON, M.D., and ARON SILVER, M.D.  
NEW YORK, N. Y.

THE finding of a positive trichina precipitin test is not in itself sufficient to justify a diagnosis of trichinosis but the fact that it often influences the observer in favor of this diagnosis cannot be denied. It may generally be stated that when the test is made there is some clinical or laboratory evidence that makes this disease suspect. For this reason a positive report may be considered, in addition to other findings sufficient to justify a diagnosis of trichinosis without resorting to further tests. In the final analysis however only a positive muscle biopsy justifies a positive diagnosis. It seems important therefore to report that in infectious mononucleosis a disease notorious for its protean clinical manifestations the trichina precipitin test has been found positive in fairly high titers in several instances. In all these the test was ordered because for one reason or another trichinosis was considered as a possible diagnosis. The first two cases which are reported in detail indicate how easy it is to be misled when undue emphasis is placed on this test.

### CASE 1—

*History*—A H, a 21 year old student nurse was admitted to the Nurses Infirmary on Feb. 18, 1947 because of sore throat and malaise. Her temperature was 100.4 and the physical findings were limited to slight reddening of the pharynx and several palpable small anterior cervical glands. The spleen was not palpable and there was no rash. A provisional diagnosis of upper respiratory infection and possible infectious mononucleosis was made. The first blood count was reported as follows: hemoglobin 81 per cent, red blood cells 4,700,000, white blood cells 12,800, neutrophils nonsegmented 12 per cent, segmented 44 per cent, lymphocyte 23 per cent, monocytes 8 per cent, basophiles 3 per cent, eosinophiles 7 per cent. There were no abnormal lymphocytes suggestive of infectious mononucleosis. Because of the eosinophilia, the count was repeated the next day and revealed 11 per cent eosinophiles. Further questioning revealed that the patient had eaten pork on several occasions within the preceding three weeks. There was no history of allergy. She had had scarlet fever at the age of 4 and rheumatic fever at the age of 9 without cardiac sequelae. At 16, the patient had pneumonia followed by empyema which did not require surgical drainage. She had lost about 15 pounds in the past three months and during this time she thought her eyelids were somewhat puffy on arising in the morning. A skin test with trichinella antigen was performed the second day and was negative. Stool examinations were repeatedly negative for ova and parasites. On the third day in the Infirmary the patient had a shaking chill with a sharp rise in temperature to 103 associated with severe muscular pains, and was admitted to the hospital.

*Physical Examination*—The patient appeared acutely ill. There were a short hacking cough, a profuse postnasal drip and a severely stuffed nose. The palpable anterior and posterior cervical glands noted on admission to the Infirmary were significantly increased in size. The heart and lungs were normal. The abdomen was soft. The spleen was not palpable. There was marked tenderness of the calf but no other evidence to suggest thrombophlebitis. No physical findings suggesting urinary tract infection were elicited.

From The Medical Service, Beth Israel Hospital and the Bureau of Laboratories, New York City Department of Health.

Received for publication Jan. 12, 1949.

*Laboratory Data*—X ray of the chest was negative X rays of the sinuses revealed a slight increase in the density of the frontal and right ethmoid sinuses Urine examinations were repeatedly negative except for the presence of acetone on two occasions when the patient was severely dehydrated after prolonged vomiting Blood counts were taken at frequent intervals and persistently revealed an eosinophilia Table I indicates the course of the shift in the white cells toward the lymphoid side Urine and blood cultures were negative While still in the Infirmary, before she became acutely ill, a specimen of blood had been sent to the Bureau of Laboratories of the New York City Department of Health for a precipitin test for trichinosis This was reported as positive in a dilution of 1 640 The test was repeated a week later and reported "serum excellent, test positive, dilution 1 640, clear cut "

*Course*—With the history of pork ingestion, fever, severe muscle pains, eosinophilia, and a positive precipitin test, it was felt that this was a case of trichinosis The patient ran a very stormy course for six days with temperature fluctuating between 100° and 104° During the second week the temperature slowly began to subside and reached normal during the third week where it remained to the time of discharge, five weeks after admission During the height of the febrile period, the patient complained of marked anorexia, occasional vomiting, and severe muscle pains On March 6, two weeks after acute onset, as the temperature was approaching normal, the peripheral blood for the first time revealed abnormal lymphocytes typical of infectious mononucleosis, and the heterophile reaction was reported positive in a dilution of 1 400 Another specimen of blood was sent to the Department of Health Laboratories and this precipitin test was negative for trichinosis Repeat heterophile reactions were reported as positive in dilutions of 1 400, and the peripheral blood showed abnormal lymphocytes on several occasions The patient's general condition rapidly improved after the third week and she was discharged in good condition Two months later, the heterophile was weakly positive 1 100, and the blood count still revealed 7 per cent eosinophiles

*Comment*—This case in retrospect, seems fairly typical of infectious mononucleosis. The rather high eosinophile counts however, sidetracked us and the positive trichina precipitin tests tended to lead us further astray. These findings and the additional corroborative evidence of pork ingestion spoke strongly for a diagnosis of trichinosis. The appearance however, of the typical blood picture for infectious mononucleosis two weeks after the onset threw doubt on the validity of the positive trichina precipitin test. The strongly positive heterophile agglutination reaction left no doubt as to the correct diagnosis, but left the positive precipitin tests unexplained. Accordingly, the third test was made and was reported negative.

CASE 2—G. G. was a 33 year old white man who consulted his physician April 1, 1948, because of severe pains in the chest back and neck. The pains were considered at the time as being muscular in origin. The physical examination was essentially negative. He was seen again four days later at which time he had fever, sore throat and chilly sensations. The physical examination was still completely negative. Because the fever could not be explained, blood was taken for the routine agglutination tests and a trichina precipitin test was done because the pain in the chest was considered to be at the site of the insertions of the diaphragm and to be muscular in origin. Three days later all tests were reported negative except the trichina precipitin test which was positive in a dilution of 1:1280. The heterophile antibody titer was 1:14. On April 10 a blood count was done to determine the presence of eosinophilia, and was reported as follows: white blood cells, 9,000, lymphocytes 66 per cent. No eosinophiles were present. The picture was reported as being suggestive of infectious mononucleosis. On April 12 a complete count was reported as follows: hemoglobin, 92 per cent, red blood cells 4,600,000, white blood cells, 9,300, neutrophils nonsegmented, 14 per cent, segmented, 15 per cent, lymphocytes 58 per cent, atypical lymphocytes, 9 per cent, monocytes, 4 per cent. These counts were considered quite characteristic of infectious mononucleosis. As a result the heterophile agglutination and trichina precipitin tests were repeated. On April 17 the heterophile was reported strongly positive in a dilution of 1:1,792. At the same time, the precipitin test was positive in the same titer as reported previously, 1:1,280. The same serum was sent to the National Health Institute at Bethesda, Md. for a complement fixation test for trichinosis. This was reported positive. A skin test done at the same time was negative.

On April 16 the white count was 24,000 with 80 per cent lymphocytes, many of which were atypical. A sternal bone marrow aspiration was reported as showing no evidence of leukemia. On this date the patient appeared and felt quite well. At no time during the illness was there an adenopathy or splenomegaly. Trichinosis was considered briefly as the diagnosis and the positive precipitin test proved quite misleading. However, the early development of the characteristic blood picture indicated the true diagnosis. The patient was not seen again until June 2, 1948 at which time the heterophile agglutination test was still positive in a high titer but the trichina precipitin test was completely negative. He appeared and felt perfectly well.

CASE 3—Mrs. R. was a 34 year old white medical research worker who on Feb. 1, 1947, began to experience a sore throat, general malaise, and muscle pains. There was no adenopathy or enlarged spleen. No blood studies were made, but on Feb. 20 the lymphocyte count was reported as 60 per cent. There was no note of a more detailed count. On Feb. 24 the heterophile agglutination test was reported positive as was also the trichinosis precipitin test. The precipitin test was negative on March 7, but the heterophile was still positive. The patient made a rapid, uneventful recovery.

CASE 4—L. Z. was a 19 year old, white stenographer who was admitted to the wards of Long Island Medical College, Feb. 20, 1947. She gave a history of fatigue and sore throat. The throat had a whitish membrane. She received diphtheria antitoxin and penicillin. She

appeared acutely ill and had a temperature of 104.0°. There was generalized lymphadenopathy, but the spleen was not palpable. The blood count on admission revealed a white count of 8,700, polys, 66 per cent, eosinophiles, 6 per cent, lymphocytes, 22 per cent, monocytes, 5 per cent, plasma, 1 per cent. Two days later the lymphocytes were 42 per cent, with many atypical forms. The eosinophilia remained at 6 per cent. The heterophile was positive at this time, as was also the precipitin test. The titers and dates of tests may be seen in Table II. The patient was discharged March 6, 1947, quite well. There seems no doubt that the patient had infectious mononucleosis. It might be mentioned here that she was Jewish and observed the dietary laws. To her knowledge she had never in her life eaten pork.

TABLE II

DATE	CASE	HETEROPHILE	PRECIPITIN
2/18/47	1		1:640
2/25/47	1		1:640
3/ 6/47	1	1:400	Neg
4/ 8/48	2	14:140	1,280
4/15/48	2	1,792:896.0	1,280
6/ 1/48	2	896:448.0	Neg
2/24/47	3	224:112.0	640
3/ 7/47	3	112:56.0	Neg
2/21/47	4	448:224.28	1,280
2/27/47	4	896:448.0	1,280
3/ 4/47	4	896:448.0	640 (faint)
4/11/47	5	896:448.0	1,280

All heterophile and trichina precipitin tests with the exception of the heterophiles in the first case were performed by the New York City Department of Health.

The three figures in the heterophile reports indicate unabsorbed serum, guinea pig kidney absorbed, and beef red cells absorbed.

CASE 5—M. C. was a white, 21 year old, male machinist who was admitted to the wards of the Long Island Medical College March 30, 1947. He gave a history of shaking chills ten days before admission. He had general malaise, muscle pains, and sore throat. He was given penicillin without effect. He appeared only moderately ill, but had a temperature of 103° on admission. There were enlarged posterior cervical glands and the spleen was one finger breadth below the costal margin. The white blood count was 5,900, with 46 per cent lymphocytes. Lymphocyte percentage rates went to 60 per cent with many atypical forms. On April 11 a heterophile agglutination test and a trichina precipitin test were done. Both were reported positive in high titers. The patient was discharged April 19 feeling perfectly well, with a final diagnosis of infectious mononucleosis. Unfortunately, no further serologic studies were made.

#### DISCUSSION

Beinstein,<sup>1</sup> in his very complete monograph of infectious mononucleosis, discusses false serum reactions in this disease. He does not, however, mention the finding of positive trichina precipitin tests in any of his cases. A review of the literature since this monograph revealed no report of this unusual finding. Beinstein pointed out that the serum substances giving false positive Wassermann reactions are probably in no way associated with the sheep cell agglutination reaction. In his own series of cases, he found that the false positive tests for syphilis often appeared before the heterophile reactions became positive. This dissociation appears also to be true in some of our cases where the precipitin tests became negative when the heterophile antibody titers were still high.

The trichina precipitin test as performed in the Bureau of Laboratories of the New York City Health Department follows the dicta laid down by the

National Institute of Health, Bethesda Md. The antigen is carefully prepared and subjected to a long process of purification. The sera to be examined are cleared of all turbidity by rapid centrifugation in a refrigerated centrifuge. Dilutions from 1:80 to 1:1280 are set up, and readings of 1:160 and up are considered presumptive evidence of trichinosis provided there is a clinical history, recent or dating up to three years back. Readings of course, may go very much higher. The value of this test is the subject of much controversy. Augustine considered it remarkably specific and had false positive reactions only when patients were taking quinine or arsenicals. It is fairly well recognized now however that false positive reactions may occur, as in periarteritis, and it has been noted to be positive at times in parasitic infections other than trichinosis. Recent reports by Fisch and co-workers<sup>3</sup> and Roth<sup>4</sup> indicate that the test is of little value and even when positive is too late to be of much diagnostic help. It is generally true that the test does not become positive until about four weeks after infestation and this should be borne in mind, but in severe cases it may on occasion become positive in a matter of days.

It is not the purpose of this report to laud or condemn the test. In its defense one might state that positive Wassermann tests occur in conditions other than syphilis but no one would suggest the test be discarded. It is essential however, that the lack of specificity of any test be known by those requesting it. Regardless of agreements and disagreements the fact remains that the trichina precipitin test is still used extensively, and to most physicians a positive report carries a good deal of weight. Skin tests are considered no more reliable and a muscle biopsy is not always feasible. It might be mentioned here that a positive biopsy may confirm the diagnosis but a negative report is not proof that the patient does not have trichinosis. The complement fixation test may be valuable but the positive report in our second case indicated that it too may prove misleading.

The blood count in trichinosis is of considerable importance. There is usually a leucocytosis and a marked eosinophilia<sup>5</sup>. However, on occasion the white count may not be elevated and in very severe cases there may be a complete absence of eosinophiles. In infectious mononucleosis the blood picture is considered to be of paramount importance. Nevertheless, the characteristic picture may not be present at the onset, and eosinophilia of a fairly marked degree has been reported<sup>6</sup>. Both of these unusual features were noted in Case 1, and to a lesser extent in Case 4.

In Cases 3, 4, and 5, trichinosis was not very seriously considered, but the positive precipitin tests proved temporarily misleading. In Cases 1 and 2 the positive tests were considered in addition to other features sufficient evidence to justify diagnoses of trichinosis. It may well be pointed out that the clinical features in these cases were not very suggestive of trichinosis, but students of this disease stress the fact that the clinical course varies greatly and indicate that the diagnosis is frequently missed because clinicians too often expect a classical history.

There would seem to be no doubt that the patients herein reported had infectious mononucleosis. In all, the blood pictures were ultimately confirmatory and in all, the heterophile agglutination tests were strongly positive. The one thing that tended to confuse in all instances was the occurrence of the positive precipitin tests. A possible explanation would be that these patients all had trichinosis whether recent or remote. This has to be given serious consideration in view of the fact that a high percentage of the population is thought to be infected. Even if the infection is not recent, it is possible to conceive of an anamnestic reaction boosting the precipitin titer. However, the very rapid return to normal in three of the cases makes this seem very unlikely, and in one (Case 4), if we may accept the history, the patient never had eaten pork in her entire life.

These patients were not found to have positive heterophile antibody agglutination tests and positive trichina precipitin tests as part of a planned study. The tests were requested by physicians before definite diagnoses were made and the findings as reported were found. The percentage of false positive trichina precipitin tests (or complement fixation tests) occurring in infectious mononucleosis is not known and would require an extensive study, but this small group indicates it would not be negligible.

Most physicians today are conditioned to the vagaries of this disease and have learned to give it due consideration in the differential diagnosis of any unexplained fever. The cases in this report stress the fact that even when it is considered, variations in the blood picture and false positive serological reactions tend to mislead. It has become more and more apparent that where the disease is once suspected, the diagnosis should be clung to tenaciously until completely ruled out or made with certainty.

#### SUMMARY

Positive trichina precipitin tests are reported in five cases of infectious mononucleosis. The evidence at hand indicates that these reactions were false positive reactions and were induced by the serum changes of infectious mononucleosis.

For permission to publish Case 2 we wish to thank Dr. J. Jerome Steinfeld and Dr. Samuel Weinbaum, New York, for Case 3, Dr. Marsh McCall, New York, for Cases 4 and 5, The Medical Department of the Long Island Medical College, New York.

## THE CHRONIC TYPHOID CARRIER II THE EFFECT OF CHOLCYSTECTOMY ON THE BACTERIOLOGIC COURSE

A LITTMAN, MS MD J A VAUGHAN PH D, AND A C IVY MD, PH D  
(CHICAGO III)

### INTRODUCTION

**I**N A previous paper<sup>1</sup> we have discussed the chronicity of the natural course of the typhoid carrier state. Because of the essential role of the carrier in the dissemination of typhoid and the infrequency of spontaneous cure of the carrier state, treatment is an important public health problem.

To date there is no effective nonsurgical therapy. In 1907 Dehler<sup>2</sup> reported the treatment of two carriers by cholecystostomy. Grunne<sup>3</sup> in 1908 described the cure of one patient by cholecystectomy. Thereafter many reports on the surgical treatment of carriers have appeared. In 1930 Roesler<sup>4</sup> compiled a very complete bibliography. Eichhoff<sup>5</sup> reviewed chiefly the European literature until 1930 and collected 102 cases in which gall bladder surgery had been employed in the treatment of the chronic typhoid carrier state. Because it was well known that the stools of some carriers do not clear up until several months after operation, he arbitrarily chose six months as a minimum follow up period for evaluation. Discarding eight cases for this reason, he found that seventy six, or 81 per cent, of the ninety four subjects were cured by operation.

Coller and Forsbeck<sup>6</sup> added eighteen cases to fifty five cases from the literature (chiefly from the United States) and reported 76.9 per cent cures for a combined total of sixty five patients surviving cholecystectomy.

The results of cholecystectomy are thus quite favorable. We have found, however, that only a few cases have been followed for a number of years after operation, and that there has been no evaluation of 'immunity' to reinfection afterward.

### THE CLINICAL MATERIAL

Of the fifteen typhoid carriers subjected to cholecystectomy eleven apparently had become infected during or after the 1939 Manteno epidemic previously described.<sup>1, 7, 8</sup> The remaining four were discovered in other state institutions and had been sent to Manteno for care. There were four male patients and eleven female patients, living in separate halves of the same isolation cottage. The dining room and kitchen facilities were shared, however. Both pre and postoperatively these patients lived with all the other typhoid carriers and were thus constantly being exposed to reinfection. This is emphasized in view of the postoperative bacteriologic course to be described.

From the Department of Clinical Science, University of Illinois College of Medicine, Chicago III, and the Manteno State Hospital, Manteno III.

We are indebted to Dr. Otto Lohman, Public Health Officer at Manteno State Hospital, for the preparation of many of the bacteriologic records.

Received for publication, Jan. 10, 1949.

*Preoperative Bacteriologic Status*—The average time between the date on which each patient was declared a chronic carrier until the date of operation was twenty-seven months ( $S D \pm 13$ ). In three subjects the duration was five, eight, and ten months, while in the remaining twelve the range was twenty to fifty-six months, averaging thirty-one months. In three instances in which the carrier state followed a diagnosed acute attack of typhoid fever, six to twelve

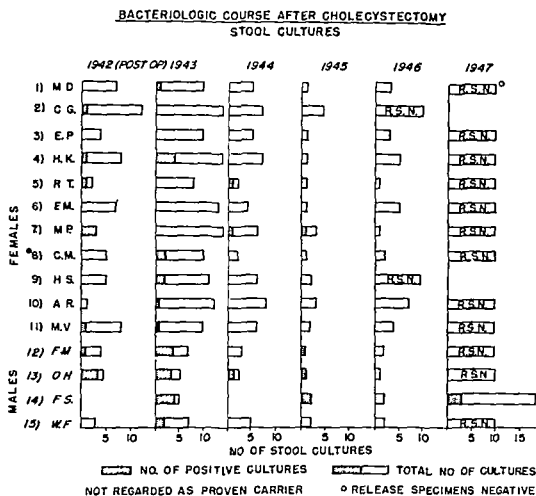

Fig 1

months elapsed between the onset of the attack and the designation as a chronic carrier. The remaining patients were designated as chronic carriers on the dates on which cultures positive for typhoid organisms were confirmed. In these patients there had been no clinical diagnosis of typhoid fever.

The preoperative bacteriologic studies on each patient are summarized in Fig 1. Each horizontal bar represents the total number of stool cultures for each subject for the year specified. The shaded portion of each bar shows the number of such specimens from which typhoid bacilli were isolated. These data are adequate to show that thirteen patients were definite chronic carriers and were excreting *Escherichia typhosa* at the time of cholecystectomy. In one patient (H K) it appears probable and in another (C M) possible that spontaneous remission had taken place. These two patients are included in the study to compare their bacteriologic course with that of the definite carriers.

Fourteen satisfactory bile cultures were made in nine cases within the eighteen-month period preceding surgery. In seven patients, or 78 per cent,

one or more positive specimens were obtained, these patients may be considered to have been biliary carriers. In two patients (C G and M P), one and two negative cultures respectively were obtained, although both patients had consistently positive fecal specimens. On the basis of so few bile samples, we considered the question of biliary infection in these two cases to have been unanswered.

Fig

The cholecystectomies were performed by Dr Arnold Selumberg between January and May in 1942. The patients were transferred from the typhoid cottage to the surgical ward a day or two before operation. As soon as the patients were ambulatory after surgery, usually within two weeks, they were returned to their previous living quarters.

#### POSTOPERATIVE BACTERIOLOGIC COURSE

Using the same descriptive scheme as in Fig 1, the postoperative bacteriologic findings are summarized in Fig 2.

*Duration of the Carrier State After Operation*—In ten cases one duodenal aspiration was made on the third to the sixth postoperative day and a bile culture taken. Typhoid bacilli were found in nine specimens. The single negative report occurred in case 9, on the fourth postoperative day. In this patient a negative stool culture had been obtained three days before operation, but there had been thirty positive cultures, including one of bile, during the preceding year. The first stool cultures made after surgery were negative in nine of the

thirteen proved carriers. These were obtained at periods ranging from two days to ten weeks postoperatively, in seven instances between the third and eighth weeks.

In three additional cases the first stool cultures were positive, and the earliest persistently negative reports were not obtained until from ten weeks to 85 months after cholecystectomy.

In one case the stools remained intermittently positive until the end of this study.

*Pattern of "Recurrences"*—From Fig 2 it is seen that in only two cases (3 and 6) were there no positive cultures obtained after surgery. In seven additional cases, only one or two positive reports were recorded.

There is a definite diminution of the number of positive cultures with the passage of time. Although the data from 1944 and 1945 are not adequate in number, comparison of the findings in 1942-1943 and those in 1946-1947 shows a striking change. In 1946-1947 in all but one case the official criteria for release from designation as a carrier were fulfilled. These, in Illinois, consist of eight negative stool cultures at consecutive monthly intervals and two negative bile cultures seven days apart taken thirty days after the last stool culture.

*Sex Difference*—The small number of cases in this group does not permit a firm conclusion regarding the relation of sex difference to cure. However, of the 100 cultures made postoperatively in the male group, twenty-five were positive, while only fourteen, or four per cent, of the 329 cultures made in the female group were positive. This difference is statistically very significant ( $\chi^2 = 40$ ), and in Fig 2 it may be seen that there is a fairly even distribution of stool sampling throughout the five-year period. This indicates, regardless of the fewness of the cases, that a sex difference probably exists.

#### DISCUSSION

The observation that *bile cultures* were positive from three to six days after cholecystectomy in nine of the ten cases tested shows that the site of biliary tract infection is not the gall bladder alone. It is not likely that infected bile expelled from the gall bladder at the time of operation would itself remain in the biliary tract for the three to six-day period described. Nor could it be presumed that in each case an infected cystic duct stump had been left behind. It appears probable that the infected bile from the gall bladder contaminated extrahepatic structures or intestinal contents and that a week or longer was required to clear the contamination.

A sufficient number of stool cultures were not taken in the early postoperative period to provide precise data on the postoperative duration of the carrier state.

*It is a remarkable and hitherto undemonstrated fact that living amid constant exposure to reinfection from untreated carriers, twelve of thirteen proved typhoid carriers became and remained cured following cholecystectomy.* In a few instances prolonged reinfections appeared to have occurred. However, most of the positive cultures obtained postoperatively, especially in the female group, appeared sporadically and for such brief periods that we believe in some

instances there may have been excretion of the organisms as transients, without definite reinfection. The transient excretion of typhoid bacilli without evidence of actual infection has been shown to occur by Cler and Ferazzi.<sup>9</sup> They reported on the stool cultures of thirty-nine persons who had been known to eat the same infected food as others who developed clinical typhoid fever. Six of the asymptomatic individuals excreted typhoid bacilli for a period up to one week after the beginning of the disease in those who developed typhoid fever. We have observed such episodes of transitory excretion of typhoid bacilli in some carriers becoming spontaneously cured.<sup>1</sup>

In a previous report<sup>1</sup> we described the bacteriologic course of seventy-nine typhoid carriers living together with the patients reported in this paper. In these seventy-nine noncholecystectomized patients who served as ideal controls for the evaluation of therapy 29 per cent of spontaneous cures occurred by the same criteria. In addition many long "recurrences" of the carrier state or lasting reinfections occurred after the carrier state had disappeared spontaneously for several weeks or months. These observations indicate that cholecystectomy was followed by a high degree of resistance to recurrence of the carrier state.

#### SUMMARY AND CONCLUSIONS

1 Cholecystectomy was performed on thirteen proved chronic typhoid carriers. Following operation these patients continued to live among many other typhoid carriers, some of whom were heavily infected. The period of study lasted five years after surgery.

2 Under these conditions of massive exposure to reinfection, twelve of the thirteen patients became and remained free of typhoid organisms.

# LABORATORY METHODS

## AN APPRAISAL OF THE MALE NORTH AMERICAN FROG (*RANA PIPIENS*) PREGNANCY TEST WITH SUGGESTED MODIFICATIONS OF THE ORIGINAL TECHNIQUE

JOSEPH N. CUTLER, B A, M A  
PHILADELPHIA, PA

### INTRODUCTION

ROBBINS and Parker<sup>1</sup> and Wiltberger and Miller<sup>3</sup> have recently described a new test for pregnancy employing as a test animal the male North American frog (*Rana pipiens*). In an attempt to evaluate the accuracy and efficiency of this new technique, the author tested 200 urine specimens from women suspected of being pregnant. Since the urine pregnancy test using the African female frog (*Xenopus laevis*) is an accepted, reliable procedure, a male *R. pipiens* and a female *X. laevis* were tested with each urine specimen, and the results compared. In addition, the advantages of Scott's<sup>2</sup> method of urine concentration are described in preparing the inoculum for *R. pipiens*.

### PROCEDURE

All urine specimens delivered to the laboratory for pregnancy testing were injected into the frogs following the technique of Wiltberger and Miller. Five cubic centimeters of whole, unmodified urine were filtered and made slightly acid to litmus with HCl. This material was injected into the dorsal lymph sac of the animal. Of the first ten animals treated in this manner, only one survived longer than one half hour. This latter animal died at the end of two hours. The high mortality could not, it seemed, be due to the toxicity of an individual urine specimen, since each animal was injected with urine from a different woman. Believing that the volume of the injection was too great to be tolerated by the animal, an attempt was made to give the urine more slowly by injection in stages 2, 2, and 1 cc at five minute intervals. This method also was unsuccessful, and 1 cc doses at five minute intervals were attempted. The animals survived the first 3 cc, but the fourth dose was almost invariably fatal within a few minutes. It was, then, apparent that if the frogs were to survive long enough to give a valid test, a small volume injection containing enough hormone to stimulate a gonadal reaction was needed to overcome the difficulty.

A modification of the original Scott method<sup>2</sup> for concentrating the chorionic gonadotropin in the urine of pregnant women has proved highly efficient when *X. laevis* is used as a test animal for pregnancy. Since it was our intention to run a duplicate test on an African frog with each American frog used (in order to evaluate the reliability of the American frog as a test animal), use of the Scott concentration method provided an inoculum suitable for both animals, thus eliminating additional urine preparation. The urine was concentrated as follows:

One hundred cubic centimeters of a first morning specimen of urine are placed in a 100 cc graduated cylinder and acidified to a pH of 4.0 using 20 per cent HCl with 0.04 per cent bromocresol green as an indicator. When the urine specimen presented for testing is less than

From the Cutler Clinical Laboratories and the Clinical Laboratories of the Community Hospital of Philadelphia

Received for publication Oct 28 1948

100 c.c., distilled water is added in the amount necessary for the recommended volume. Urine specimens of less than 50 c.c. are rejected as unsuitable, since our experience with several hundred tests on *X. laevis* has shown that such small quantities of urine do not usually contain the necessary titer of hormone to produce a positive reaction, especially in very early pregnancy. Also, urines with a specific gravity of less than 1.015 are usually unsuitable for testing, giving rise to a large percentage of false negatives unless a full 100 c.c. of urine are available. In the latter case a specific gravity of 1.010 is satisfactory. To the acidified urine, 5 c.c. of a 20 per cent suspension (in water) of acid washed kaolin are added, followed by thorough mixing (inversion of the cylinder twelve times is sufficient). Acid washed kaolin may be prepared,\* or it may be bought already prepared†. We have been using the Baker preparation with excellent results.

The cylinder is set aside until the kaolin has settled out to a volume of 15 to 20 c.c., at which time the supernatant urine is siphoned off and discarded. The sedimented kaolin is transferred to a test tube and packed by centrifuging at moderate speed for about five minutes. The resultant supernatant is discarded. Five cubic centimeters of 0.1N NaOH are added to the packed kaolin and the kaolin is redistributed through the alkali by vigorous stirring with a glass rod. When thoroughly mixed the kaolin alkali suspension is spun in the centrifuge at high speed for about five minutes or until the supernatant is clear. The clear supernatant is poured over into a test tube and made pink by the addition of 1 drop of 0.5 per cent alcoholic phenolphthalein solution. Twenty per cent HCl is added drop by drop until the pink color is just discharged. The solution is ready for injection. The foregoing procedure should consume no more than thirty to forty five minutes.

The use of the concentrated urine as a test inoculum for *R. pipiens* has given excellent results. One cubic centimeter of concentrated urine is injected into the dorsal lymph sac with no ill effects upon the animal observed. Since the 1 c.c. of concentrated urine represents a volume of 20 c.c. of whole urine its use is most advantageous in low hormone titer early pregnancy urine specimens. However concentration of the urine may lead to false positive reactions in menopausal urine specimens with high follicular stimulating hormone titers. Where menopause is suspected urine giving a positive reaction should be checked using either a rabbit or an African frog or by injecting two 2½ c.c. doses of whole urine into *P. pipiens* at one hour intervals.

#### TECHNIQUE FOR R. PAPIENS TEST

One hundred cubic centimeters of a first morning urine specimen are prepared by the Scott method and 1 c.c. of the final product is injected into the dorsal lymph sac of the frog (see Fig. 1). The animal is then placed in a clean dry glass receptacle (a 1000 c.c. beaker is ideal) covered with a weighted wire mesh top to prevent escape of the animal. At the end of one half hour, the frog is grasped firmly in the left hand, and the right leg of the animal is imprisoned between the operator's index and second fingers. The animal's left leg is taken between thumb and index fingers of the operator's right hand, and the leg is drawn up close to the frog's side. The frog's cloaca is then brought in contact with a clean glass microscope slide. The slide is immediately transferred to the microscope stage and the drop of urine examined under either the low or high dry objective. The sperm cells are easily recognized with either magnification. In a positive test, the sperm cells are shed in large numbers and can be seen actively thrashing about, or quiescent with their long whiplike tails waving slowly back and forth. In a negative test there are, of course, no sperm cells.

\*As described in *Practical Physiological Chemistry* Hawk & Bergelin ed. 11 page 63 footnote.

†From J. T. Baker Chemical Company Phillipsburg N. J. as Kaolin Washed Powder (American Standard).

The urine is quite clear, except for occasional red blood cells and one or more of a variety of intestinal parasites harbored by the frogs. These latter in no manner resemble the sperm cells and should not be mistaken for them. If at the end of the first half hour the urine shows no sperm cells, the procedure is repeated at half-hourly intervals until three hours have elapsed from the moment of injection. Absence of sperm cells within the three-hour period constitutes a negative test.

Fig 1—Diagram illustrating site and method of injection for *R. pipiens* pregnancy test

#### ACCURACY OF *R. PIPIENS* AS COMPARED WITH *X. LAEVIS*

Unselected urine specimens brought to the laboratory were concentrated. A male *R. pipiens* and a female *X. laevis* were inoculated with the urine concentrate. Results were observed and compared.

In a series of 200 urine specimens from women suspected of being pregnant, two American frogs gave false negative reactions where *X. laevis* injected with the same urine specimens gave positive tests. Conversely, two *X. laevis* frogs gave false negative reactions with urine specimens that reacted positively on

the male *R. pipiens*. This constitutes a record of 99 per cent accuracy for both species of test animals since the combined results by the laboratory tests were all checked and substantiated by later clinical findings. Of the 200 urine specimens tested, 130 were from women thought to be thirty to thirty five days pregnant (ten to fifteen days after first missed menstrual period) thus proving the ability of the *R. pipiens* test to detect conception as early as any of the tests now in routine use.

#### DISCUSSION

In our opinion, the pregnancy test using *R. pipiens* is far superior to any of the routine tests now in use. It is an exceptionally reliable test. In our analysis of 200 urine specimens only two false negative results were encountered. These two failings occurred early in our investigation when we were trying to reuse animals which had already given one positive test, after a five day rest period as recommended by Wiltberger and Miller<sup>3</sup>. It was found inadvisable to reuse the animals for the following reasons: (1) A positive reaction appears to exhaust the frog's supply of sperm cells. Resting the frogs long enough to regenerate new sperm cells involves a time interval within which manition and wasting occur. This is due as Robbins and Parker<sup>1</sup> point out, to the impracticability of providing the proper live insect diet for the animals under laboratory conditions. (2) The animal is so inexpensive and its supply so readily available that it is false economy to salvage the frogs for reuse, thereby risking unreliable results. In cases where urine specimens have proved negative for pregnancy, we have reused the animals involved with consistently reliable results, but it is recommended that such animals be returned to their storage tank in the refrigerator and not kept at room temperature. After instituting the policy of not reusing previously positive animals 150 urine specimens were analyzed for pregnancy using *R. pipiens* as the test animal without any further false negative (or false positive) reactions.

The care necessary for the use of *R. pipiens* is simplicity itself. A small fish aquarium (14 in. by 10 in. by 8 in.) will easily house up to twenty frogs. Such a tank conveniently fits into the lower compartment of even a small laboratory refrigerator, where the animals are stored at about 10° C. in one half inch of water until ready to use. While in the refrigerator, the animals are in a state of hibernation and will survive for weeks on end without feeding. Aside from keeping the water level constant in the tank, there is no other care necessary for *R. pipiens*. One hour prior to use in a test, a frog is removed from the tank and placed in a suitable wire mesh covered receptacle at room temperature. This short thawing period is sufficient to return the animal to metabolic activity necessary for the test. In practice, we remove the frog for thawing as soon as the urine for testing reaches the laboratory. By the time the urine is concentrated and ready for injection, the frog is ready, too. Storage of *R. pipiens* at room temperature for more than a day or two is not recommended. At the beginning of our studies we stored all our frogs at room temperature. We found that wasting and inanition were quite rapid, especially during the warmer summer months, but most disconcerting was the high spontaneous mortality rate of the unused frogs, at times as high as 50 per cent within two or three days.

after receiving the animals from our supplier. An occasional spontaneous death occurs among the refrigerated animals, but it is an infrequent occurrence.

The rapidity with which the results of the test develop is, in our opinion, the most remarkable feature of this new technique. Using 1 cc of the concentrated urine as our inoculum, we have observed positive reactions consistently within one-half to three-quarters of an hour after injection of the animal. Even allowing up to one hour for concentration of the urine, results of the test can be obtained in less than two hours from the time the specimen reaches the laboratory. This compares with a minimum of forty-eight hours for the standard Friedman test and up to eighteen hours for the *X laevis* test.

The advantages of using whole, unmodified urine in any pregnancy test are obvious. Although we attempted such a procedure, as described by the originators of the test, the results (mentioned elsewhere in this report) in our hands were discouraging. Robbins and Parker<sup>1</sup> describe the same difficulty with what they call "toxic urines," but apparently the rate of mortality from injection among their frogs was not as great as that which we encountered. They further decry the lack of adequate methods for detoxifying the urine specimens. It is our opinion that the large volume of the prescribed inoculum (5 cc) for such a small animal is responsible for the high frog mortality and not the presence of toxic substances in the urine. By use of the Scott method,<sup>2</sup> a small volume inoculum (1 cc) representing the hormone content of 20 cc unmodified urine is provided and at the same time substances toxic for the frog are removed. The latter is accomplished by the ability of acid-washed kaolin at pH 4.0 to selectively adsorb the protein materials from the urine, leaving behind the toxic substances in the supernatant which is discarded. This phenomenon has demonstrated itself to our satisfaction inasmuch as we have not had a single technical fatality among our frogs since substituting the concentrated specimen for whole unmodified urine. Once the necessary reagents for Scott's method<sup>2</sup> are at hand, the actual preparation of the urine for injection is neither technically difficult nor excessively time consuming, and the fact that each test goes to its desired conclusion without mishap, requiring the use of only a single animal, more than compensates for the necessary preparation of the urine.

The originators of the *R. pipiens* pregnancy test emphasize the fact that as yet they have not determined whether a seasonal variation in the reactivity of the frog might be encountered, especially during the breeding season. From their report, it is to be presumed that their investigations ran through the fall and winter of the year. Our experiments began in the early spring and continued throughout the summer months until the end of September. Apparently this would complete the cycle of one full year and would include the breeding season of the American frog. During the seven months from the beginning of March until the end of September, we encountered no variation in the reactivity of the animal to the gonadotropic hormones involved in the urine pregnancy test. These results, coupled with those of Robbins and Parker,<sup>1</sup> and Wiltberger and Miller,<sup>3</sup> would seem to indicate that *R. pipiens* can be used throughout the year as a reliable test animal for urine pregnancy testing.

## SUMMARY

The use of whole unmodified urine as a test medium for *R. pipiens* is not entirely satisfactory, resulting in the death (in our hands) of the animal when given the necessary 5 cc dose.

Concentration of the urine by Scott's method yields an ideal medium for *R. pipiens*. The medium is nontoxic with 100 per cent survival of the test animal throughout the testing period. Moreover the accuracy of the test is enhanced by providing a greater concentration of hormone, a particularly valuable consideration in very early pregnancy.

Scott's method for concentrating the urine is described in detail as well as the actual technique in carrying out the test on *R. pipiens*.

Reuse of animals which have given a positive test may lead to false negative results in the second test. For this reason reuse of such animals is not recommended. Animals which upon previous testing yielded negative results may be reused safely after a twenty-four hour rest period.

An attempt to evaluate the reliability of *R. pipiens* as a test animal has been made by injecting a standard test animal (*X. laevis*) and a *R. pipiens* male frog simultaneously with the same urine specimen and then comparing the resultant reactions. Both species of animals produced a record of 99 per cent accuracy proved clinically.

The seasons of the year covered in this report (early spring to early autumn) in conjunction with the reports of other investigators working through the fall and winter would indicate that there is no seasonal or breeding period variation in the animal's response to gonadotropic hormone.

With modifications in the original technique (described in the body of this report), the pregnancy test using male *R. pipiens* frogs has proved itself in our hands, to be exceptionally reliable so much so that it has replaced *X. laevis* and rabbits in our laboratory. In addition the shorter reaction period, the exceptionally low cost of the animal, the ready availability of supply, and the minimum of laboratory care and housing of *R. pipiens* make it in our opinion the animal of choice in urine pregnancy testing.

# AN IMPROVED TECHNIQUE FOR THE TRANSMISSION OF THE LANSING TYPE VIRUS OF POLIOMYELITIS IN MOUSE EXPERIMENTS

CHESTER L. BYRD, JR  
CHICAGO, ILL

MANY attempts were made to shorten the incubation period of poliomyelitis infection in animals<sup>1 2 3</sup> Most of them were directed to the production of a *locus minoris resistentiae* in the central nervous system by traumatizing the brain tissue Another trend is to increase the amount of material injected by the intracerebral route This amount is, however, limited by topographic and special conditions Attempts to increase the usual dose administered in one injection from 0.01 ml to 0.03 ml have not been successful as yet According to our own experience, approximately 0.01 ml of the injected material is lost by back-seepage if 0.03 ml is injected Thus the problem is twofold first, there is a necessity to produce brain trauma by such means as will not kill the animal or weaken the virus, second, the amount of injected material has to be increased by administration in a different manner from the accepted and routine injection into one side of the brain

In order to achieve this end, it was decided to inject the infective material into both sides of the mouse cranium Different sites were selected as points at which to pierce the skull Preliminary experiments have shown that the largest number of mice survive when the injections are given exactly at a point halfway between the outer corner of the eye and the center of the external acoustic meatus

When the Lansing type of virus of poliomyelitis is transferred from mouse to mouse, brain emulsions are used It was mandatory, therefore, to use brain emulsions from normal, noninfected mice to determine the mortality rate due to trauma when using the described route of injection

One hundred twenty-five mice were inoculated with 0.03 ml of a 10 per cent emulsion of brain from normal mice on both sides of the cranium Only three (i.e., 2.4 per cent) of the mice died as a result of the inoculation Thus this method of administration seemed to be satisfactory

Most workers prefer clear suspensions when propagating the virus of poliomyelitis by injecting brain material of one mouse into another This is achieved by grinding the brain with alundum or other suitable material in buffered saline, filtering through gauze, and centrifuging off coarse particles<sup>4</sup> Finally, the supernatant is inoculated into the brain of another animal

In addition to attempting to increase the brain trauma, we also tried to change the preparation of the infective material by the following means

The brain was ground with unbuffered saline in a mortar without alundum or other similar material The volume of the saline used for this was ten times

---

From the Hektoen Institute for Medical Research of the Cook County Hospital  
Received for publication Nov. 12, 1948

larger than the volume of the brain. After thorough grinding the material was poured into a test tube and left to stand in the icebox for thirty to sixty minutes. Then 0.03 ml. of the supernatant was injected into each side of the head of the mouse by piercing the skull at a point halfway between the outer corner of the eye and the center of the external acoustic meatus.

Young, Plymouth strain Swiss mice were used for the experiments. The Lansing type of virus was received by the courtesy of Dr. S. O. Levinson, from the Michael Reese Research Foundation. Table I shows the results of experiments in which the classic technique and our modifications were compared. It is well evident from the tabulations that the technique described here gives superior results.

TABLE I

MATERIAL INOCULATED	NUMBER OF MICE	ID	INCUBATION PERIOD	AVERAGE TIME TO PRODUCE 50% MORTALITY	NUMBER OF MICE DEAD FROM TRAUMA
Lansing virus, crude suspension, bilateral inoculation	100	1/10 <sup>6</sup>	5 ± 3	4 ± 1	2
Lansing virus crude suspension, unilateral inoculation	40	1/10 <sup>5</sup>	10 ± 6	6 ± 2	1
Lansing virus in buffered saline pH 4.0, unilateral inoculation	40	1 × 10 <sup>4</sup>	12 ± 6	8 ± 2	1
Mouse brain, without virus bilateral inoculation	125	0	0	0	3

Number of days between inoculation and onset of paralysis

It has to be added that in spite of the larger traumatization due to the bilateral inoculation, the mortality of mice due to mechanical factors was very low.

While the results achieved by the use of this technique were very satisfactory, it has to be considered that the clinical picture of traumatism of the brain, i.e. contralateral paralysis developing early after the injection, cannot be evaluated in animals after material has been introduced into both sides of the cranium. This may cause difficulties in the evaluation of the results.

#### SUMMARY

An improved technique was described for the propagation of the virus of poliomyelitis from mice to mice. This method consists of injecting less purified suspensions in unbuffered saline bilaterally into the brain.

# A METHOD FOR THE DETECTION OF LACTOSE IN URINE

ANDREW A. ORMSBY, PH D, AND SHIRLEY JOHNSON  
GALVESTON, TEXAS

IT IS common experience in clinical laboratories that the published methods for the detection of lactose in urine are unsatisfactory. Fermentation tests are preferable to others but, unless carefully performed and interpreted, may lead to false conclusions. The chemical methods, which should serve at least to confirm the results of fermentation studies, are found to be wanting in both sensitivity and specificity. Among the many chemical procedures which have been described is the methylamine test<sup>1</sup>. Urine suspected of containing lactose is boiled with a small amount of methylamine and then made strongly alkaline with NaOH, a red color indicates the presence of lactose. As described, the method is not sensitive and results cannot be consistently reproduced.

A study of the factors affecting the methylamine reaction has indicated that, under the proper conditions, this test can be made very sensitive, and the results are so reproducible that, with certain refinements of procedure, it may be adapted to the quantitative determination of lactose. By the methylamine reaction we are able to detect quantities of lactose which are not detectable by the usual Benedict's test for reducing sugars.

## PROCEDURE

To 5 ml of urine add 1 ml of a 0.2 per cent aqueous solution of methylamine hydrochloride, and 0.2 ml of 10 per cent NaOH. Mix by inversion or gentle swirling. Cover the tubes with glass bulbs or marbles and place in a water bath at 56° C for thirty minutes. Remove from the bath and allow to stand at room temperature.

If the urine contains much lactose a red color will be apparent before the heating period is completed. The color increases as the tubes are allowed to stand at room temperature, reaching a maximum in about an hour. Hence, if the concentration of reducing sugar is low it is best to observe the tubes after they have been allowed to stand for some time.

## DISCUSSION

*Sensitivity*—An intense red color is observed after fifteen to twenty minutes at 56° if the urine contains 0.5 per cent lactose. This is a concentration which gives a Benedict's reaction usually interpreted as one plus. A 0.05 per cent solution of lactose in urine, which is negative with Benedict's reagent, gives a slight but definite positive reaction after standing for thirty minutes at room temperature. In order to detect traces of lactose it is best to run a control, containing water in place of methylamine, in order to avoid confusion caused by the color of the urine.

From the Department of Biochemistry and Nutrition and the Clinical Laboratories of the John Sealy Hospitals, University of Texas Medical Branch.  
Received for publication Dec. 20, 1948.

*Other Sugars*—The only sugars which give a red color in the methylamine reaction are the reducing disaccharides. The only members of this group which have been found in urine are lactose and maltose. Maltose, which has been reported as occurring in a few instances, seldom has been identified definitely. Glucose, fructose, xylose, galactose and sucrose in large amounts give a yellow color which is readily distinguished from the lactose reaction.

*Temperature and Alkalinity*—Although a more intense color is produced at higher temperatures the interpretation of the results is made difficult because of an interfering color caused by caramelization of the sugar. A temperature of 56° maintained for thirty minutes gives an intense color with lactose and causes little caramelization as shown by the slight color of the blank. This temperature was chosen because it is close to the optimum and baths at this temperature, used for inactivation of serum, are generally available in clinical laboratories.

The optimum amount of NaOH was found to be 0.2 to 0.4 ml. of a 10 per cent solution. Since, however, the larger amount causes an increased blank color, it is advisable to use only 0.2 milliliter. If the amount of 10 per cent NaOH added is either larger or smaller than 0.2 to 0.4 ml., the intensity of color given by lactose is decreased.

*Aeration*—It was noted in the original description of the methylamine reaction<sup>1</sup> that the color is decreased if the tubes are violently shaken. This result has been confirmed and it is therefore advisable to avoid aeration. For this purpose the contents of the tubes are mixed gently and, during the heating period, are kept covered.

*Effect of Ammonia*—The concentration of ammonia has a marked effect on the intensity of color produced by a given amount of lactose (Table I). In the table the amount of methylamine added is smaller than that recommended when using the reaction to detect lactose in urine. The concentrations of methylamine and lactose were adjusted to give intensities which could be read on the Klett-Summerson colorimeter, using a No. 54 filter.

TABLE I 5 ML. 0.3 PER CENT LACTOSE 0.5 MG. OF METHYLAMINE HYDROCHLORIDE 0.2 ML. 10 PER CENT NaOH HEATED AT 56° FOR 30 MIN., READ AFTER STANDING 1 HR.

Mg. NH <sub>3</sub> N added	0	0.2	0.4	0.5	1.0	5.0	10.0	15.0	20.0
Readings	5	86	91	109	121	246	32	0	0

It is evident that increasing amounts of ammonia up to 5 to 10 mg., enhance the color, but if addition of ammonia is continued, color development is completely inhibited. Ammonia, in the absence of lactose gives no red color, but appears to increase the yellow color ascribed to caramelization; this effect again increasing until 10 mg. of NH<sub>3</sub> N have been added and then falling off to zero.

It is unlikely that the presence of ammonia in fresh urine would cause inhibition of color development from lactose, since this would require greater than 2 mg. ammonia N per milliliter of urine, an unlikely concentration. It is possible, however, that if urine is allowed to stand until bacterial decomposition

of urea has progressed markedly, that a concentration of ammonia great enough to produce inhibition might be reached. In such a case the ammonia is readily removed with permutit.

*Quantitative Determination of Lactose*—Preliminary experiments have indicated the feasibility of applying the methylamine reaction to the quantitative determination of lactose. In this case the factors of temperature and alkalinity must be carefully controlled. In addition, the amount of ammonia present must

Fig 1—Absorption spectrum of color produced in the methylamine reaction. The broken line represents the spectrum of the blank. A Cenco-Sheard Spectrophotometer with a 1 cm cuvette was used.

be known and adequate compensation provided. The ammonia may be determined and enough added to the standards to equal the amount present in 5 ml of urine. A better procedure appears to be the removal of ammonia from the urine with permutit, and then the addition to blank, standards, and urine sample of 5 mg of ammonia-N, thus utilizing the ammonia to increase the sensitivity of the method.

If the method is to be used quantitatively it is necessary to compensate for the color of the urine by using a blank containing urine, but no methylamine. A determination of the absorption spectrum of the colored substance (Fig 1) shows two absorption maxima, at 425 and 540 millimicrons. Although there is greater absorption at 425 mμ, the blank also shows great absorption at this wave length, whereas at 540 mμ the blank exhibits scarcely any absorption. Readings are, therefore, made with a filter having its greatest transmittance at 540 millimicrons.

## SUMMARY

1 The methylamine reaction can be utilized, under the correct conditions for the detection of small amounts of lactose in urine

2 Preliminary experiments indicate that the method might be adapted to the quantitative determination of lactose

## A VISCOSITY-EFFUSION METER FOR MEASURING THE CONCENTRATION OF ANESTHETIC GASES

R. N. HARGER, PH. D., EUGENE S. TURRELL, M. D., AND J. MARTIN MILLER, M. D.  
INDIANAPOLIS, IND.

PUBLISHED methods for estimating the concentration of ether and other anesthetic gases in air, or air plus oxygen, are not suitable for routine use in the operating room. For determining ether both chemical and physical analytic procedures have been described. The former include the combustion method of Spence,<sup>1</sup> the method of Nicloux,<sup>2</sup> later modified by Shaffer and Ronzoni,<sup>3</sup> in which the ether vapor is absorbed in 50 per cent sulfuric acid and subsequently oxidized with dichromate, and the iodine pentoxide method of Haggard.<sup>4</sup> The time required to complete such chemical analyses renders the results of little immediate use to the anesthetist. Physical methods which measure the increase in gas density caused by the presence of ether have been reported by Boothby,<sup>5</sup> who used the Waller<sup>6</sup> gas balance, and by Harger and co-workers,<sup>7</sup> employing a modified Cady<sup>8</sup> gas balance. These vapor density methods yield immediate results, but the necessary apparatus is too cumbersome to be used except for research where trained technicians are available to operate the gas balance. Kruse<sup>9</sup> determined ether in air by means of the Guthrie analyzer,<sup>10</sup> using concentrated sulfuric acid to absorb the ether, and Seevers and associates<sup>11</sup> used the gas analysis apparatus of Burrell, Seibert, and Jones<sup>12</sup> to determine cyclopropane in air, employing fuming sulfuric acid as the absorbent for cyclopropane. These methods, which measure contraction in gas volume following absorption of the anesthetic gas, require a technician and take some time.

In an effort to develop a very simple, rapid, automatic analytic method for anesthetic gases we have experimented with a number of physical procedures. We first used twin flowmeters operated in series with a tube containing activated charcoal between them to absorb ether vapor, the apparatus being essentially that of Strache and co-workers<sup>13</sup> as modified by Sauter.<sup>14</sup> This gave fairly good results but required the constant use of the absorbent. Next, we tried methods depending upon the decrease in viscosity produced by ether, either by measuring the rate of flow through a capillary tube at constant pressure, or by determining the change in pressure between the capillary ends at constant flow. We then substituted for the capillary tube a fine orifice in a thin plate\* which would measure change in rate of effusion caused by alteration of gas density, in conformity to Graham's law.<sup>15</sup> The effusion molecular weight apparatus of Eyring<sup>16</sup> is a somewhat recent application of this principle. In our hands both viscosity

From the Department of Biochemistry and Pharmacology, Indiana University School of Medicine.

This work was partly supported by the Riley Memorial Association.

Received for publication Nov. 26, 1948.

\*We are indebted to Mr. Charles Ness of the Linde Air Products Company, Indianapolis, Ind., for constructing our first orifices.

and effusion methods gave quite satisfactory readings but it was found somewhat difficult to maintain constancy of air flow or pressure differential.

Finally, we found that these difficulties could be avoided by an arrangement which registers the combined changes in viscosity and density. Our apparatus is a modification of the device described in 1920 by Viehoff<sup>17</sup> for determining the concentration of carbon dioxide in flue gas. In Viehoff's apparatus the gas to be analyzed is drawn through a capillary tube and then through a fine orifice. Using a common suction, ordinary air is drawn through an identical tube and orifice, and a manometer connecting the two limbs by means of side arms placed between the capillary and orifice registers any pressure difference between the two limbs. Since carbon dioxide has a higher density than air its presence reduces the rate of effusion through the orifice in the flue gas limb, while the lower viscosity of carbon dioxide as compared with air causes a decrease of the resistance to the passage of gas through the corresponding capillary tube. These changes in effusion and viscosity are additive and result in an increase of gas pressure in the flue gas arm of the apparatus thus producing a rise in the manometer on the air side. According to Dennis and Nichols<sup>18</sup> the presence of moisture and other impurities interferes somewhat with the accuracy of the method when used for flue gas. The Viehoff viscosity effusion bridge has been employed by Jenkins<sup>19</sup> for determining the levels of both oxygen and carbon dioxide inside an oxygen therapy chamber.

Since ether also has a higher density and a lower viscosity than air or oxygen, the differences being much greater than for carbon dioxide, this procedure somewhat modified was found to be admirably suited for the determination of ether.

When using the Viehoff apparatus to analyze the rebreathed gas from an anesthetic machine, one cannot employ air as a reference gas since the oxygen content of the rebreathed gas is frequently far above 21 per cent, so that an absorbent must be constantly used for one limb. For this reason we have modified the apparatus by using only one of the twin limbs and connecting the manometer to the two ends of the capillary tube. The presence of ether causes a marked drop in the manometer level. To establish the base line the inlet is provided with a two way stopcock by means of which one can momentarily shunt the gas through a tube containing charcoal or other suitable absorbent. This base line changes rather slowly during a surgical operation so that an occasional adjustment will suffice. In order to maintain a constant flow for a given gas mixture, the suction employed distal to the orifice is kept above the critical point of about 40 cm. of mercury (Saint Venant and Wantzel<sup>20</sup>). The apparatus is extremely simple and operates automatically, giving prompt continuous readings of the concentration of ether vapor.

The method was found to be satisfactory for the determination of nitrous oxide, cyclopropane, and ethylene in the presence of nitrogen or oxygen. Nitrous oxide and cyclopropane each has a higher viscosity but a lower density than oxygen or nitrogen while ethylene has about the same density as air but a much lower viscosity. With a ternary mixture of nitrogen, oxygen and one of these

gases the per cent of oxygen must also be determined, but this can be accomplished quickly with the Pauling-Beckman apparatus<sup>21</sup> Helium in an oxygen may be measured by our effusion-viscosity device The much lower density of helium causes a marked rise in the manometer column The apparatus will also indicate the approximate percentage of oxygen in nitrogen, but with the manometer used for ether the change in level is small The reason for this is that the density and viscosity of oxygen are both slightly higher than for nitrogen so that the two changes act oppositely Since the viscosity effect is greater than the density effect, the result is a small rise in manometer reading when oxygen is added to nitrogen

One also can use the apparatus to determine both nitrous oxide and ether and cyclopropane and ether when these pairs are present in the gas mixture, since one may selectively remove the ether, thus obtaining a second reading for the ether-free gas However, since the total manometer drop exceeds the sum of the drops due to ether and nitrous oxide or ether and cyclopropane, it is necessary to employ a table or nomogram constructed from observed manometer readings with various mixtures of ether-nitrous oxide or ether-cyclopropane in an oxygen Our data for this purpose are not yet complete

#### DESCRIPTION OF APPARATUS

The type of apparatus which we have used is shown in Fig 1 The example described has an air flow of about 100 cc per minute, and a manometer height of 52 cm, which gives a drop of about 1 cm for each per cent of ether For compactness it is mounted on a vertical board 24 in long and 5 in wide, having a horizontal base 8 in long located on the back and about 10 in from the lower end In this way the apparatus projects only about 16 in above the table on which it is clamped, a part of the manometer being below the table level A small shelf for supporting the manometer bottle is located at the bottom of the vertical board The various parts are as follows

*Capillary Tube*—This tube (*A*) is 50 cm long with a bore of 0.67 mm and with the intake end sealed to a glass H For conserving space the capillary is bent in the form of a U, with care taken to avoid constricting the bore while bending The outlet from the capillary (*A*) is connected to the orifice (*B*)

*Variable Resistance to Gas Flow (D)*—This arrangement, described by Hofsass,<sup>22</sup> is placed at the intake of the capillary tube The variable resistance is a piece of 27 gauge (0.4 mm diameter) nichrome or platinum wire extending a short distance into the lumen of tube (*A*) The position of the wire may be adjusted by means of a gastight metal screw attached to the top of the wire Since the only gas pressure at this point is that required to draw the gas through the absorption tubes, it is not difficult to secure a gastight joint for this adjusting screw One can use a small glass rod sealed to the wire, which slides inside a rubber sleeve

*Orifice*—The orifice (*B*) is placed between the exit of capillary (*A*) and the suction tube (*C*) This orifice has a diameter of 0.12 mm and is drilled in a sheet of platinum 0.01 in thick, using a special drill for this purpose\* The sheet of platinum is bolted between two opposing brass plates so that the orifice is between two brass tubes soldered into holes in the centers of the plates Gaskets of thin sheet tin are used to insure tightness A plug of cotton is placed in the line immediately ahead of the orifice so that dust particles will not collect on the orifice and change its diameter

\*This drill was obtained through the kindness of the National Jet Company Cumberland Md

Fig 1—Diagram of viscosity effusion meter

**Manometer**—This is connected to side arms just beyond the two ends of the capillary tube. It is of the reservoir type the glass tubes having an inside diameter of about 3 millimeters. The reservoir is a 2 oz widemouthed bottle with an inside diameter of about 3.6 cm and is fitted with a two hole rubber stopper. In this way more than 99 per cent of the shift in manometer level occurs in the glass tube on the right. We use a free flowing manometer oil having a specific gravity of 0.827 and containing a red dye.\*

**By pass for Absorption**—A two way stopcock (E) with a 2 mm bore is attached to the inlet end of the capillary (A) so that the gas to be tested may enter through the plain tube (G) or through the absorption tube (F) which contains a layer of the absorbent followed by calcium chloride. The reason for the calcium chloride in tube (F) is that charcoal and other absorbents frequently give off some moisture. Stopcock (E) is lubricated very lightly with a silicone grease, avoiding any of the lubricant in the lumen.

\*This manometer oil is sold by The Meriam Instrument Company, Cleveland, Ohio.

*Tube for Removing  $H_2O$  and  $CO$* —This tube (*H*) through which the gas first passes is filled with soda lime followed by calcium chloride. None of the anesthetic gases which we have tested is absorbed by calcium chloride or soda lime.

*Source of Suction*—One can use an ordinary good water aspirator with a trap in the line to prevent the backflow of water due to changes in water pressure. Since the apparatus as described has a flow of only about 100 c.c. per minute, we have used as a portable source of suction a strong 10 gal. steel drum which had been evacuated with a water pump. This drum is provided with a closed end mercury manometer so that one can make sure that the pressure inside it is always less than about 350 mm. of mercury. To avoid collecting ether vapor in this drum we use a large absorption tube containing charcoal which is placed in the suction line (*C*) between the drum and the orifice.

*Joints Between Parts*—All joints through which the gas passes before it escapes through the orifice should be as nearly glass to glass as possible since rubber rapidly absorbs ether and other anesthetic gases. Such absorption causes a lag in reaching the correct reading.

*Connection for Anesthetic Machine*—This is a metal tube about 3 in. long, machined to fit between the end of the hose from the mask and the metal hose connection of the machine. This tube has a metal side arm with an internal diameter slightly larger than that of a piece of capillary tubing with about 2 mm. bore which connects the inlet of tube (*H*) with the breathing tube of the anesthetic machine. This glass connecting tube is pushed inside the side arm of the metal sleeve so that its end is flush with the lumen of the breathing tube, and the connection between the glass and metal tubes is made gastight by means of a rubber sleeve.

#### PROCEDURE

Unscrew adjusting rod (*D*) so that the lower end of the wire is in the enlarged portion of the capillary tube (*A*). Connect the vacuum source to (*C*) with air entering at (*H*). The exact degree of partial vacuum is immaterial, so long as it is below 40 cm. of mercury. The manometer should now register 45 to 48 cm. above the reservoir level. Lower the wire of (*D*) until the manometer reads 52 centimeters. This is the *reference point* for all measurements with this particular apparatus. Mark this point on a sheet of cardboard mounted next to the manometer tube. Connect the inlet with the gas mixture to be analyzed, opening the stopcock of the gas container before connecting it to the apparatus. Turn stopcock (*E*) to shunt the gas through the absorbent in (*F*). After waiting about thirty seconds to allow the entering gas to flush out all gas previously in this limb of the apparatus, read the manometer level. If it is not at the reference point of 52 cm., adjust the variable resistance (*D*) until the level is exactly at this point. Now turn stopcock (*E*) so that the gas enters through tube (*G*), making sure that the stopcock lumen is fully open. When the manometer reading is constant, which usually occurs in about fifteen seconds, record the fall, or rise, from the reference point, measured in centimeters. Repeat the procedure with various other concentrations of the anesthetic gas and use the data to plot concentration against manometer deviation from the reference point. The resulting curve will approach a straight line. This curve may be used to construct a scale for the instrument, the ether scale being shown in Fig. 1.

The absorbent for ether alone should be 12 to 24 mesh activated charcoal, which will absorb about one third of its weight of ether before allowing any to pass. With cyclopropane, tube (*F*) is replaced with an absorption tube containing pumice impregnated with concentrated sulfuric acid. For mixtures of ether and cyclopropane the apparatus inlet is provided with a third limb containing an activated fuller's earth absorbent, Florisil,\* followed by calcium chloride, and tube (*F*) contains pumice impregnated with sulfuric acid. When the gas is shunted through tube (*F*), this absorbs both ether and cyclopropane. When shunted through the third tube (not shown in Fig. 1) the Florisil absorbs ether but, except for the first few seconds, no cyclopropane.

\*The Florisil was kindly furnished by the Floridin Company, Warren, Pa.

For nitrous oxide and ethylene the manometer depression is read with the reference point set for air or oxygen. This is because we have found no satisfactory absorbent for either of these gases. Furthermore their concentrations during anesthesia are usually too high for them to be removed for any length of time.

#### PREPARATION AND STORAGE OF SPECIFIC GAS MIXTURES

Since ether and other anesthetic gases readily enter and pass through rubber and other plastics and dissolve in water and most other fluids except mercury, it is necessary to mix and store these gases in materials which are impervious to them. Our gas mixtures were prepared and stored either in flexible aluminum bags devised by us or over mercury in a glass container. These two procedures will be briefly described.

Fig. —Parts and assembly of flexible aluminum gas bags

*Flexible Aluminum Gas Bags*—The parts and construction of these bags are shown in Fig. 2. The bag material is sheet aluminum 0.001 to 0.0015 in. thick covered on one side with a heat sealing plastic (Pliofilm or Metalum). The material was purchased in a 100 ft. roll 18 to 36 in. wide\*. This sheet aluminum is manufactured for hermetically sealing coffee, drugs or articles which may be injured by exposure to moist air. As commonly used, two identical rectangles are cut from the sheet and the substance to be preserved is placed between them with the plastic surfaces facing each other. Heat from a laundry iron is then applied around the periphery of the sheets which causes them to seal together where heated, forming a gastight joint. Since we found that ether was somewhat absorbed by the plastic coating, we employed an arrangement involving a minimum of exposure of the plastic on the interior of the bag. A rectangle a little over twice the size of the finished bag is cut

\*This sheet aluminum coated with a heat sealing plastic was purchased from The Debeckum Company, Cleveland, Ohio.

from a sheet. This is laid on the table with the plastic side down. Along each edge of the sheet a strip about  $\frac{3}{4}$  in wide is then folded over and pressed down as shown in the sketch. The sheet is then doubled together to form the bag, making sure that the exposed plastic coated strips on the upper half are superimposed on those of the lower half. Before the sealing operation, a reinforcement for the inlet is sealed to the outside of one side of the bag, holes of proper size are cut in this reinforced portion, and the inlet is bolted in place, using thin sheet tin gaskets to insure tightness. The two halves are then sealed together.

Fig 3—Ether vaporizer

with a hot laundry iron, using a sheet of paper between the iron and the plastic surface, after which a binder about 1 in wide is sealed to the four edges of the bag. If properly made these bags are absolutely gastight. After continued use they develop small pinhole leaks and should be discarded. However, a bag having a few very fine leaks may still be used provided the gas inside it is kept under slight pressure by placing a newspaper or rather large towel on top of the bag. As valves for these bags we use an unlubricated, well ground, Pyrex stopcock. The glass tube of the stopcock should fit fairly snugly inside the copper inlet tube and should be pushed two or three inches into this tube using a rubber sleeve to make a tight joint between the two. In this way very little gas inside the bag comes in contact with the rubber sleeve. When stored in these bags, mixtures of air, oxygen, or nitrogen with ether or the other anesthetic gases retained a constant composition for several hours.

*Filling the Bags With Specific Gas Mixtures* With ether, the liquid (absolute) is run from a microburette into a closed glass vaporizing tube about  $4\frac{1}{2}$  in by 1 in (Fig 3) with its lower half placed in water heated to around  $60^\circ$ . A short vertical inlet tube with a side arm is sealed to the top of the vaporizing tube. The microburette has a long, tapering tip which extends through this vertical tube, the joint between the burette and vertical tube being closed with a rubber sleeve. A second tube, which serves as the outlet, extends almost to the bottom of the vaporizing tube. Air, oxygen, or nitrogen to be mixed with the ether

enters the side arm of the inlet tube and the mixture with the ether vapor then emerge through the outlet tube which connects to the gas bag with all joints as nearly glass to glass as possible. The introduction of the liquid ether should be finished shortly before the last of the other gas is run through the vaporizing chamber in order to transfer all of the ether vapor to the bag. A calibrated flowmeter measures the rate of flow of the gas entering the vaporizing tube. One cubic centimeter of liquid ether when vaporized will occupy 232 c.c. at 21 and 760 millimeters. From this figure corrected for existing conditions of temperature and barometric pressure one can calculate the volume of liquid ether required to prepare the desired concentration of the vapor after it is mixed with a given volume of the other gas. In calculating the resulting per cent of ether vapor in the mixture one must correct for the increase in volume due to the addition of ether vapor. After being filled with the gas mixture, the bag should be gently kneaded to mix the contents. To further insure complete mixing the gas should be allowed to remain in the bag about ten minutes before it is used.

With compressed anesthetic gases the tank valve or a suitable reducing valve is connected to a flowmeter calibrated for this particular gas. The stream of gas from this flowmeter enters a Y tube where it meets a stream of air, oxygen or nitrogen the speed of which is also controlled by means of a second flowmeter. When the rates of the two gas streams are properly regulated the outlet of the Y tube is connected with the gas bag. When using this procedure we commonly prepare from 1 to 10 liters of the gas mixture.

As an alternate method for measuring the required volume of a given gas, one may employ a dry gas meter constructed from a 100 c.c. hypodermic syringe by cutting off a suitable length of the inner end of the plunger and using this section of the plunger as a piston discarding the remainder of the plunger. The piston should be of such a length that a one hole rubber stopper which closes the open end of the syringe serves as a stop when the inner end of the plunger exactly reaches the 100 c.c. mark. The open end of the piston is closed with a well fitting cork which is inserted so that its exposed end is just flush with the end of the piston. If the piston is left open it will take a longer time to flush out the apparatus when changing gases. The syringe is mounted in a horizontal position. The two ends of the syringe are connected by glass tubes to a special stopcock which is bored to reverse the direction of flow for each 90 degree turn of the handle. To avoid a significant increase in pressure within the syringe while turning the stopcock a dry 50 c.c. hypodermic syringe is mounted in a vertical position with its opening at the bottom and connected through a T tube to the line between the tank and the syringe gas meter. Any gas which collects in this vertical syringe at the end of an excursion of the piston in the 100 c.c. syringe will be added to the latter syringe in the next stroke of the piston. With a well made syringe the gas pressure required to operate this meter is no greater than that needed for a standard wet gas meter, and there is practically no gas leakage between piston and barrel. This apparatus equipped with an automatic reversing valve will be described in a separate paper. The graduations on the 100 c.c. syringe should of course be properly checked with a good gas burette.

*Glass Chamber for Preparing and Storing Gas Mixtures Over Mercury*—This apparatus is shown in Fig. 4. Our gas chamber has a volume of 1125 c.c. with the mercury level at (X). A dry, well fitting Pyrex stopcock with 4 mm. bore (1) is sealed to the top of the chamber. Just beyond the stopcock the tube branches. The vertical limb (B) is for inserting the tip of a 2 c.c. burette (C) through the bore of the stopcock (1). A rubber sleeve makes a gastight joint between tube (B) and the burette. Sealed to the horizontal limb is the female portion of a 12/30 standard taper Pyrex joint (D). The male portion of joint (D) is sealed to a glass T the long arm of the T being a capillary tube (E) with 2 mm. bore which serves as delivery, or inlet for the chamber. The dry glass joint which is held together with rubber bands permits a vertical motion of tube (E). The horizontal limb of the T (F) is constricted and joined through a rubber sleeve to the outlet of a dry 100 c.c. glass syringe with part of the plunger cut away leaving the remainder as a free moving piston. This piston serves as a pressure equalizer so that gas leaving the chamber is always at atmospheric pressure. The pressure tubing connecting the chamber and the leveling bottle is fitted with a screw hose clamp.

*Ether Mixtures* The gas to be mixed with ether is stored in an aluminum bag and is kept under a slight positive pressure by placing a magazine or large towel on the bag. Open stopcock (A) and elevate the leveling bottle. Unscrew the hose clamp and allow the mercury to completely fill the chamber and ascend past the stopcock almost to the level of (D). Close stopcock (A) and the hose clamp. Connect the gas bag to (E) leaving the bag valve closed. By means of a 50 cc dry syringe withdraw gas through (B) until syringe (G) is empty. Now open the gas bag valve and withdraw about 50 cc

Fig. 4—Glass chamber and accessories for preparing and storing gas mixtures over mercury

of gas to flush out the tubes. Disconnect the 50 cc syringe and quickly close (B) with a glass rod. Completely open stopcock (A), lower the leveling bottle, and momentarily open the hose clamp to permit the mercury to descend about an inch, and then close the hose clamp. Remove the rod from (B) and quickly insert the burette (C) which contains anhydrous ether, making sure that the ether fills the tip. The burette stopcock is lightly lubricated with a silicone grease. The tip of the burette should project about 1 cm below stopcock (A). Slightly unscrew the hose clamp to permit a slow inflow of the gas during the introduction of the ether, and then run in the desired volume of liquid ether. Next, with the gas still entering slowly at (A) quickly remove the burette and close (B) with the glass rod. Close stopcock (A) and lower the mercury level to about the middle of the chamber so as to vaporize all of the ether. After about five minutes open stopcock (A), unscrew the hose clamp, slowly lower the mercury level exactly to (X) and then close the hose clamp. As soon as the gas in the chamber reaches atmospheric pressure, close stopcock (A). Allow the mixture to stand fifteen minutes to insure complete mixing. From the chamber volume (1,125 cc) and the volume of liquid ether introduced, calculate the per cent of ether vapor in the mixture. Checks of such mixtures with a modified Cady gas balance and other methods showed excellent agreement between calculated and observed results. Once made, such a mixture will retain a constant composition for days.

*Mixtures of Other Anesthetic Gases* As with ether, the diluting gas is stored in an aluminum bottle. Accurately measure the necessary volume of the anesthetic gas with the syringe gas meter previously described or by means of a mercury filled gas burette and then introduce it through tube (B). Run in the diluting gas through tube (E) as with ether.

Fig 5—Manometer drop for various concentration of ether in nitrogen and in oxygen (5. cm base line)

Before connecting delivery tube (H) to the viscosity effusion meter close tube (B) with a glass rod and withdraw gas from (E) until syringe (G) is empty. Then open stop cock (A) and with the leveling bottle somewhat elevated slightly open the hose clamp to permit a slow escape of gas from the chamber. Next turn on the viscosity effusion meter with air passing through it and then connect the inlet tube of the meter with tube (E). Regulate the flow of mercury into the chamber so that the piston of syringe (G) is about at the mid point. This piston greatly facilitates the transfer of gas from the chamber to the meter.

**Caution regarding gas mixtures!!!** Ether cyclopropane and ethylene when mixed with air or oxygen are highly inflammable and in contact with a hot spark they will explode with great violence. Avoid flames or sparks in the vicinity of such mixtures!!!

#### VISCOSITY EFFUSION METER READINGS WITH KNOWN CONCENTRATIONS OF ANESTHETIC GASES

The results with ether in the presence of nitrogen or oxygen are shown in Fig 5. The mixtures were prepared and then composition checked, as described in the preceding section. It will be noted that the readings for ether in oxygen are about 3 per cent higher than those for ether in nitrogen, with both curves approaching straight lines. Since the oxygen content of re-breathed gas during anesthesia with ether is usually at least 50 per cent, the scale for ether was constructed from a curve midway between the ether nitrogen and the ether oxygen curves, which was shown to be the curve for ether in 1 1

Fig 6 —Manometer shifts for certain gases in nitrogen (52 cm base line)

Fig 7 —Manometer drop produced by cyclopropane in air and in oxygen (62 cm base line)

N + O In this way the readings are within 99 and about 101 per cent of the correct figure

Fig 6 gives the results for binary mixtures of nitrogen with ether, cyclopropane, ethylene, nitrous oxide, carbon dioxide, and oxygen. In the case of oxygen the results represent a rise in manometer reading, the others being a fall. In all cases the reference point was set at 52 cm with nitrogen only. If

Fig 8—Manometer drop for ternary mixtures of nitrous oxide, nitrogen and oxygen (62 cm base line with reference point set for air. Oxygen percentages are for cyclopropane free gas.)

the manometer depression for ether in nitrogen is expressed as 1.0, the relative depressions produced by the same concentrations of the other gases are, respectively: cyclopropane, 0.51; ethylene, 0.29; nitrous oxide, 0.22; and carbon dioxide, 0.20, with a rise for oxygen of 0.043.

Various mixtures of cyclopropane and oxygen were run with a second viscosity effusion meter having a reference point of 62 centimeters. The results (Fig 7) show that the readings with oxygen are all about 8 per cent higher than with air. In determining cyclopropane during anesthesia one should also determine the per cent of oxygen and use a curve of the type of Fig

Fig. 9—Concentration of ether and oxygen in rebreathed gas during six surgical operations. Percentages are for the gas after removal of water and carbon dioxide.

7 to read the correct per cent of cyclopropane. The per cent of oxygen may be determined with the Pauling-Beckman oxygen meter, or by comparing the reading of the cyclopropane-free gas with that for air and calculating the oxygen content from the type of oxygen-nitrogen curve shown in Fig. 6.

Ternary mixtures of  $N_2O$ ,  $O_2$ , and  $N_2$  were also tested with the viscosity-effusion meter having a reference point of 62 cm with this reference point set for air. The results are given in Fig. 8. To determine the per cent of nitrous oxide during anesthesia, one should note the depression below the base line for air produced by the  $N_2O$ ,  $O_2$ ,  $N_2$  mixture and also determine the per cent of oxygen with the Pauling-Beckman oxygen meter. From these two results and the curves of Fig. 8 one can calculate the per cent of nitrous oxide.

Viscosity-effusion meter readings of ternary mixtures of ether-cyclopropane-oxygen and ether-nitrous oxide-oxygen are now being obtained. When such

surveys are completed we should be able to construct tables or nomograms to enable one to use the viscosity effusion meter to determine both ether and cyclopropane and ether and nitrous oxide when these pairs are used for anesthesia

#### CONCENTRATIONS OF ETHER AND OXYGEN DURING SURGICAL ANESTHESIA

Measurements with a viscosity effusion meter were made on the rebreathed gas from an anesthetic machine during a large number of surgical operations where ether was the only volatile anesthetic used. For the ether determinations the reference point was set with the ether free gas. Oxygen determinations were run on the ether free gas with the reference point set with air. Fig 9 gives the results for six of these cases, which illustrate some of the variations observed. It will be noted that, following the induction period, the concentration of the ether during the remainder of the operation ranged from 2 to 3 per cent for Case 5 to 5 to 7 per cent for Case 3. In all of the cases the oxygen content of the rebreathed gas was high, ranging from 70 to 80 per cent during most of the operation.

Results with a much larger series of ether anesthetics will be presented in a separate paper.

#### REMARKS

The particular sizes of capillary and orifice which we have employed were chosen to give a small flow of gas and to produce a manometer depression of about 1 cm per cent of ether. Here the capillary furnishes a little over 7 per cent of the total resistance to gas flow, the remainder being in the orifice assuming that the effective pressure drop across the orifice is 40 cm of mercury. The rate of gas flow may be varied, as desired, by varying the diameter of the orifice. Our experiments indicate that if the fraction of the total resistance to gas flow contributed by the capillary is kept constant the manometer reading for a given gas mixture will be the same, and, therefore, the same scale may be used for all instruments having this ratio of resistance between capillary and orifice. In other words, any instrument with a reference point of 52 cm of oil (sp gr 0.827) should give the readings shown in Figs 5 and 6. If one desires a higher or lower, manometer reading for the reference point this can be produced by varying the length or diameter, of the capillary. The effect will be to increase or decrease, the scale divisions, the change in scale divisions being proportional to the change in reference point manometer reading. While our data in Figs 5 and 6 should enable one to construct a scale for any instrument we suggest that each instrument be calibrated with a few concentrations of anesthetic gas to be read with it.

A rise in temperature slightly increases the manometer level for a given gas because of an increase in viscosity and a decrease in density. This rise for the 52 cm reference point is about 1.7 mm of oil per degree. Since most operating rooms are kept at a fairly constant temperature and the reference point is occasionally checked, and adjusted, if necessary, any error due to temperature changes will be insignificant.

The manometer drop for ether in nitrogen or oxygen is greater than the calculated drop, assuming that the viscosity and density of the mixture are strictly additive for the ratio of gases used. Tests with certain mixtures indicated that the deviation is due to altered viscosity. Various investigators<sup>23</sup> have reported that the viscosity of certain binary gas mixtures deviates from that calculated on a simple additive basis. Fortunately, this deviation is about the same for ether-nitrogen and ether-oxygen so that varying the oxygen-nitrogen ratio makes very little difference in the manometer drop for ether.

Our methods for preparing and storing specific concentrations of anesthetic gases in nitrogen, oxygen, or nitrogen plus oxygen have been described in detail because some other workers have reported considerable difficulty in these matters. Thus Haggard<sup>24</sup> states: "In carrying out the work presented in this series of papers, the author has been repeatedly confronted by a situation similar to Spence's. Carefully prepared ether-air mixtures have given an analysis of almost exactly one-half the calculated figure. A prolonged and unsuccessful effort has been made to account for the discrepancy in the results."

Using the methods described in the preceding pages, our ether mixtures gave analytic figures which agreed almost perfectly with the calculated values.

We have not yet tested some of the newer homologues of diethyl ether but there seems to be no reason why this apparatus may not be used for the determination of these compounds in mixtures with air or oxygen.

#### SUMMARY

1 This paper describes a simple apparatus for continuously indicating the concentration of certain anesthetic gases during surgical anesthesia.

2 The rebreathed gas from an anesthetic machine is passed through a capillary tube and then through a fine orifice. An oil manometer, bridging the ends of the capillary tube, registers the combined effect of changes in viscosity and density due to the concentration of the anesthetic gas.

3 The gas flow through the apparatus is about 100 c.c. per minute and the suction distal to the orifice needs only be maintained above about 400 mm. of mercury.

4 Since changes in oxygen concentration cause a small shift in the manometer base line, the entering gas is occasionally shunted through a tube of charcoal or other absorbent in order to adjust the base line.

5 The apparatus will accurately record the concentration of ether, cyclopropane, ethylene, and nitrous oxide when these are singly present in nitrogen or nitrogen plus oxygen. It will also indicate the approximate concentration of oxygen in nitrogen.

6 The procedure may be modified to determine the concentration of two of these anesthetic gases in rebreathed air.

7 Methods are described for preparing specific concentrations of anesthetic gases in nitrogen or nitrogen plus oxygen. For storing these mixtures without appreciable loss, a flexible aluminum gas bag was developed.

8 Readings obtained with the instrument are presented showing the concentration of ether and oxygen in the rebreathed gas during six surgical operations.

## A MODIFIED LOEFFLER'S MEDIUM FOR CULTIVATING CORYNEBACTERIUM DIPHTHERIAE

THEODORE C BUCK, JR  
BALTIMORE, MD

SINCE Loeffler<sup>1</sup> first published his formula for cultivating *C. diphtheriae*, numerous modifications of his medium have been reported. In 1932, Pai found that a coagulated egg medium supported growth of the *Corynebacterium* for all diagnostic purposes. Pai's medium had the disadvantage that a great many surfaces were irregular and pitted with air holes, with resultant losses of media batches.

For the past several years a modified Loeffler's medium, with incorporated egg, has been used successfully in this laboratory. This medium is superior to the routine Loeffler and the Pai media both in the cultivation of *C. diphtheriae* and in the demonstration of chromogenesis. Because of the many requests which we have received for our formula, it was decided to submit it for publication.

### EXPERIMENTAL

In the study of Pai's medium it was thought that the growth-promoting factor supplied by egg was a sulfur derivative. However, incorporation of sulfur-containing amino acids into our routine Loeffler's Trypticase medium<sup>3</sup> showed no significant additional growth promotion. Accordingly, trials were made in which whole fresh egg, previously beaten for about five minutes with a rotary egg beater, was added in varying quantities to the Loeffler medium.<sup>3</sup> The media were then inoculated with test organisms. Best results were obtained with a ratio of one whole fresh egg added to 1 liter of medium.<sup>3</sup>

### THE FORMULA

Trypticase (Peptone)*	20 Gm
Salt	5 Gm
Dextrose	10 Gm
Water	500 cc
Heart infusion broth (double strength)	500 cc
Whole egg (well beaten)	1

Ox serum was added in the ratio of 3 parts to 1 part of the broth formula. The pH was then adjusted with 2 per cent dipotassium phosphate, about 30 milliliters. It is important to obtain a pH of 7.8 to 8.0 before inspissating. The final pH, as determined in the water of syneresis in the bottoms of the tubes after inspissating, should be pH 7.6 to 7.8.

From the Bureau of Laboratories, Baltimore City Health Department.  
Received for publication Dec 30 1948.

\*Baltimore Biological Laboratory's product.

## COMPARISON WITH ROUTINE MEDIUM

Microscopic observations of approximately two hundred smears made from virulent and avirulent strains grown on the modified medium, in comparison with the routine medium,<sup>3</sup> showed the metachromatic bodies to have an intensified color and to be more brilliant and more sharply defined when stained with Loeffler's methylene blue. The large bizarre types A, B and C of Westbrooke<sup>4</sup> were markedly differentiated as were the polar and bipolar bodies.

The growth phase was enhanced. Perceptible growth is generally observed on the new medium and not on the routine at the end of four or five hours of incubation at 35° C. Smears made from these young cultures showed even more marked chromogenesis than described.

The modified medium, prepared as described is now used routinely in this laboratory. A dehydrated form is also commercially available.\*

## AN EXPANSILE NEEDLE FOR THE INTRODUCTION OF INTRAVENOUS CATHETERS

ALFRED P. FISHMAN, M.S., M.D.\*  
CHICAGO, ILL.

CARDIAC catheterization usually entails the sacrifice of a peripheral vein. During the course of the procedure, a peripheral vein is isolated surgically, incised for the introduction of the catheter, and finally ligated. A wide-bore needle has been employed to pass the catheter into the vein, but its use necessitates a small catheter and a large vein. A split needle† capable of being expanded following its entry into a vein makes it possible to insert wide-bore catheters through the puncture opening, minimizes surgery, and permits subsequent reutilization of the same vessel. The manipulations incident to the passage of the catheter are reduced to those involved in venipuncture.

The needle (Figs 1 and 2) consists of three parts: an outer split shell, a shaft, and a central stylet. The shell consists of two halves joined by a screw device to permit retraction from, and approximation to, the inner shaft. Its proximal end is adapted to receive the end of a syringe barrel. The shaft is a fine-bore, thick-walled needle with sharp tip, to which the shell is clamped by clockwise rotation of the screw. The fine stylet closes the lumen in the shaft.

In practice, the assembled needle is inserted through the incised skin into the vein lumen. The vein is not dissected free, its posterior attachments are left intact. Following insertion of the needle, its position in the vein lumen is verified by withdrawing the central stylet. If free blood flow is observed, the stylet is replaced, the shaft is withdrawn, the vein puncture opening spread by rotation of the screw, and the catheter inserted. The catheter is then advanced as the needle shell is withdrawn. At the termination of the procedure, following removal of the catheter, bleeding is usually minimal and readily controlled by pressure and Gelfoam.

The needle has been used successfully a number of times in dog and man for the introduction of cardiac catheters. The external jugular vein in the dog has been catheterized at weekly and semiweekly intervals. Gross examination has revealed scarring at the site of previous puncture with patency of the vessel lumen above and below the scarred zone.

Fig 1

Fig 2

The residue from the acid extraction was suspended in 1 ml of water and then 4 ml of 95 per cent alcohol were added. The suspension was thoroughly mixed and centrifuged, and the supernatant was decanted. The residue was washed four times with 5 ml of 95 per cent alcohol and then three times with 5 ml of a boiling ether alcohol mixture. The supernatant and washings were collected and made up to 25 ml with alcohol. This fraction contains the ether alcohol soluble phosphorus and consists chiefly of phospholipids (Fraction 2).

The residue from the ether alcohol extraction was suspended in 2.5 ml of 1N KOH and the mixture incubated for twenty hours at 37° C. To the resulting clear solution, 0.6 ml of 6N HCl and 3 ml of 5 per cent trichloroacetic acid were added. The precipitate formed was separated by centrifugation. The supernatant contains the pentose nucleic acid and phosphorus from the phosphoprotein. This was decanted and made up to 10 ml with distilled water (Fraction 3).

The desoxyribonucleic acid remains with the residue and was brought into solution by boiling with 5 per cent trichloroacetic acid. The residue was separated and discarded. The supernatant was made up to 10 ml and designated the desoxyribonucleic acid fraction (Fraction 4).

Duplicate 0.5 ml aliquots of each fraction were dried under an infrared lamp and the phosphorus was then determined quantitatively in each case, using the method of King.<sup>7</sup> Counting of the radioactivity was done with a thin walled mica window counting tube and standard scaling assembly. The number of counts per 100 Gm, divided by the milligrams of phosphorus per 100 Gm is designated the "specific activity" of the fraction.

A series of *in vivo* counts over the tumor sites were also made on each patient at varying intervals after administration of the test dose. These counts were made with a standard gamma tube and scaling circuit. *In vivo* counting was surprisingly successful despite the fact that P<sup>32</sup> emits only a high energy beta particle (1.7 mev).

## RESULTS

Table I shows the quantitative uptake of P<sup>32</sup> by tumor as compared with normal brain tissue in ten subjects with intracranial tumor. Table II shows the fractionation of tissue phosphorus in four subjects studied by this technique. It is clear from these data that there has been an increase in concentration of the phosphorus in the tumor tissue in every instance as compared with the normal brain, the ratios vary from 1.6:1 to 29:1. The highest concentration obtained after intravenous injection is 19:1 in subject CA, in which case the white matter appears to be slightly less active than the gray matter. In general there appears to be a rough correlation between the phosphorus uptake and the anti-

pated metabolic activity of the tissue as judged on the basis of the degree of malignancy. In the fractionation studies likewise concentration by the tumor exceeds that by normal brain in every instance but one (Subject SK, Fraction 4). Concentration of phosphorus in Fraction 4 is lower than the others, as would be expected, but rises with the passage of time as indicated by the second biopsy in Subject SK. The lack of any concentration in Subject AW (Table I) is due to the fact that the tumor had been removed surgically several days before administration of the phosphorus and the specimen was obtained from the area immediately underlying the area of removal which was subsequently shown histologically to be free of tumor tissue.

In vivo counts were only moderately successful with the apparatus used thus far. Increased counts over the tumor sites were recorded quite consistently but the ratios of increase were small and the localizing value of this technique for diagnostic purposes is to be determined.

# DISCUSSION

A period of several years would be necessary to evaluate properly any therapeutic effect that may be obtained from the radiation derived from this isotope and such information is not available at the present time. To anticipate a beneficial response, selective absorption of the isotope in high concentration by the tumor tissue is a prerequisite but, in addition, a high stability of its incorporation in cell protoplasm with a low turnover rate is also desirable. In this connection, phosphorus incorporated in nucleoprotein is known to be more stable than that in the phospholipid or ester fractions. For this reason our

interest centers chiefly about the more stable intranuclear and cytoplasmic phosphorus of Fractions 3 and 4 (vide supra). Desoxyribonucleic acid (fraction 4) occurs chiefly in the nuclei of cells and is believed to serve an important function in cell division. Ribonucleic acid (Fraction 3) is a constituent of cytoplasm and nucleoli of cells and appears to play a dynamic part in metabolic activity, especially in those cells in which active protein synthesis is occurring. There is some reason to believe<sup>8</sup> that the desoxyribonucleic acid of the nucleus is formed at the expense of cytoplasmic ribonucleic acid, and since the rate of this reaction correlates with the rate of tissue growth,<sup>9</sup> it may be inferred that the nuclear fraction is built up during mitosis. Blues, Tracy, and Cohn<sup>10</sup> have shown that desoxyribonucleic acid phosphorus is very stable in the nongrowing organ. Its rate of turnover is surprisingly slow, especially in contrast to that of the ribonucleic acid fraction. These same authors have demonstrated the rate of desoxyribonucleic acid phosphorus accumulation in experimental hepatoma to be intermediate between resting and regenerating liver. If these data are applicable to malignant brain tumors, the higher metabolic activity of growing neoplastic cells might be expected to show a greatly augmented phosphorus metabolism, leading finally to a sharp rise in the more stable nuclear fraction. Based upon the same reasoning, it might also be anticipated that repeated administration of  $P^{32}$  to maintain a constant supply of inorganic isotopic phosphate in the metabolic pool would lead to the accumulation of a higher desoxyribonucleic acid phosphorus ( $P^{32}$ ) concentration than could be obtained from a single dose of the isotope. Thus, on theoretical grounds there is some justification for the administration of thirty doses of 333 microcuries each, in preference to a single dose of 10 millicuries, if a sustained radiation effect for therapeutic purposes is to be maintained. This principle should be equally applicable to any rapidly growing malignant tumor by virtue of its high metabolic and growth rates. In any clinical use of  $P^{32}$  the capacity of normal, metabolically active tissues, especially bone marrow, to withstand the radiation will be the limiting factor. Additional investigation of this principle demands further attention.

#### SUMMARY

1 Inorganic phosphate containing  $P^{32}$  was administered parenterally to patients with malignant intracranial tumors.

2 Biopsy material was obtained, after which, by means of standard chemical techniques, the ratio of concentrations of radioactivity in tumor and normal brain tissue was shown to rise to as high as 19:1.

3 Chemical fractionation of tissue phosphorus showed a small but significant concentration in the nucleoprotein of both cytoplasm and nucleus. The implications of these findings are discussed.

# TISSUE RESPONSES TO PHYSICAL FORCES

## II THE RESPONSE OF CONNECTIVE TISSUE TO PIEZOELECTRICALLY ACTIVE CRYSTALS

SILAS M. EVANS, M.D., AND WALTER ZEIT, PH.D.  
MILWAUKEE, WIS.

### I INTRODUCTION

THE manner in which biologically active dusts produce fibrotic reactions in tissues has stimulated much thought and research. The development of this problem has been reviewed frequently, most recently by Machle.<sup>1</sup> There is general agreement among authors that present explanations cannot be reconciled with all experimental and clinical observations. The observations unexplained will be recalled later in this discussion.

The interrelationship between various endogenous and exogenous fibrotic stimuli has increased the complexity as well as the importance of this problem. It is recognized that the biologic activity of quartz dust and of tuberculosis is interchangeable and "symbiotically" additive.<sup>2</sup> Crystalline cholesterol and other "endogenous" substances bear similarly interchangeable relationships with quartz and the phospholipid of tuberculosis.<sup>3</sup> Fibrogenesis appears to be a common response to many stimuli. Indeed, fibrogenesis seems to be influenced more by biologic variation and the site of involvement than by the specificity of its stimulus.

Since different stimuli produce a common biologic response, it appears that apparently dissimilar fibrogenic stimuli might share some "common denominator." This notion is strengthened by the interchangeability of quartz and tuberculosis, and by the increased response produced by adding one to the other.

We have assumed that, if a living organism survives, its response to injury is purposeful. An examination of the functional qualifications of a reaction should, therefore, provide valid inferences as to the nature of the injury. Fibrous tissue has not been demonstrated to offer a barrier to the diffusion of substances in solution beyond that usually offered by the tissue it replaced. Fibrous tissue has not been shown to detoxify a toxin, neutralize a poison, or fix an antigen. While young fibroblasts are possibly related to phagocytosis, phagocytosis is hardly a functional defense against a "poisonous solution." It is apparent that a fibrous reaction is not able to offer functional defense against the "slowly soluble poison" which is considered by most investigators to be the mechanism of injury in silicosis.<sup>1</sup>

Fibrous tissue in normal physiology provides structural support against stress in a physical sense. Fibrous proliferation should, therefore, be stimulated by stress or the need for support. The osteoblast clearly responds along

From the Departments of Medicine and Anatomy, Marquette University School of Medicine.

Received for publication Feb. 1, 1949.

stress vectors as is so plainly shown in the architecture of long bones. Perhaps its parent cell, the fibroblast, is similarly responsive.

The architecture of the silicotic whorl conforms closely with the equations of force. This is clearly demonstrated by its similarity to the stress lines depicted with a magnet and iron filings. (This is illustrative and is not intended to imply that magnetic force is thought to be fibrogenic.)

Perhaps the notion that fibrous reactions are best equipped to confine stress is what led early observers to the "sharp point" view of silicosis. Were "sharp points" the functional stimulus, one would expect the reaction to stop when the points were blunted rather than continue beyond any apparent need.

## II. THEORETICAL CONSIDERATIONS

As has been stated already, fibrous tissue proliferations function as supportive components in normal body economy and are best qualified to fill this role in disease as well. It also has been emphasized that even as fibrous tissue responds along stress vectors in normal growth, it also distributes itself architecturally in close conformity with Newton's "equations of force" when it forms the predominant reaction to an injury. These observations, though elementary, clearly demand that a careful search for a factor of stress in the physical sense be made wherever fibroblasts proliferate in a superfluous manner.

As stated in a preliminary paper<sup>1</sup> it has been observed that there is a direct relationship between the ability of a dust to produce a fibrotic reaction in tissue and the crystal symmetry of the dust. Asymmetrical (piezoelectric) dusts are observed to be fibrogenic whereas symmetrical (nonpiezoelectric) dusts are benign.

Piezoelectricity is that property of certain solid materials which effects when conditions are proper a transference between electrical and mechanical energy states. This transference operates in either direction. As an example, it is this property of quartz which permits the use of quartz crystals in phonographs where energy is converted from a mechanical vibration produced by the record's groove to the electric current which energizes the loud speaker.

It is necessary to present some definitions of terminology to be used in the discussion of the piezoelectric phenomenon as it relates to biology.

*Piezoelectricity*—Piezoelectricity is the property possessed by some crystals, of developing electric charges when compressed or extended in particular directions. Conversely when a potential difference is applied to suitable points on such a crystal, it expands or contracts. Piezoelectric properties can occur in all crystals lacking a center of symmetry.

It may be stated with authority<sup>6a</sup> that molecularly symmetrical crystal material cannot possess piezoelectric properties. When matter exists in a crystal which has no point of central molecular symmetry it is then potentially qualified as piezoelectric.

All crystals exist with a molecular orientation which classifies them in one of thirty-two classes. Only those crystals belonging to classes lacking a

central point of symmetry can be piezoelectric. In a preliminary report<sup>4</sup> it was shown that, where data are available, benign dusts uniformly belong to symmetrical crystal classes, while fibrogenic dusts belong to asymmetrical classes. A few special instances of dusts requiring further comment as apparent exceptions will be considered later. Approximately 10 per cent of minerals existing in nature have molecular orientation compatible with the property of piezoelectricity.

One must consider what sources of energy might activate the mechanism if the fundamental stimulus in fibrous reactions is considered as a transformation of noninfluential energy states through piezoelectricity to forms of energy which comprise biologically influential stress. There are several possible sources of energy which suggest themselves.

- 1 Electromagnetic fields may exist in nature continuously or in "bursts" in sufficient concentration and at proper frequency to produce mechanical distortions of receptive particles within tissue.

- 2 Electropotential reversals occurring in normal physiology could produce momentary physical distortion in receptive particles.

- 3 Fluctuant pressure variations secondary to pulsant circulation, respiration, cough, strain, position change, etc., might induce polarity and electric current on a receptive particle.

- 4 Within a deposition composed of many packed particles, either response in one particle might induce the opposite response in any neighboring deposit within its sphere of influence.

- 5 Thermal variations within the animal can produce variations in electropotential and distortions in shape in receptive crystals (secondary piezoelectric effect).<sup>6b</sup>

There have been many clues recognized by biologic observers that lead one to believe the conventional description of a biologic environment is incomplete. This topic will be discussed later in the light of intensity and frequency of the energetic field within which the host is situated.

Purely for test purposes, a number of "postulates" for a fibrosive dust have been conjectured. These are listed at this point as they summarize in a practical manner the theoretical considerations so far presented.

*"Postulates" for a Biologically Fibrosive Dust —*

- 1 *Relative insolubility* in body fluids to allow particles to remain in situ long enough to be effective.

- 2 *Asymmetrical crystal class* compatible with piezoelectric properties.

- 3 *Electrically nonconductive* as conductivity will "short circuit" and nullify the piezoelectric effect.

- 4 *Proper particle size*, small enough to be energized by existing concentrations of force fields, yet not so small that they be "out of reach" of existing electromagnetic frequencies or so small that their induced strain might be "subfibrogenic."

- 5 *Sufficient particle concentration* per unit mass of tissue so as to allow sufficient magnitude of physical effect to stimulate the reaction, or to allow

reciprocal physical influence between the unit particles, thereby permitting the deposition to become a system operating in resonance

### III EXPERIMENTAL PROCEDURE

The purpose is (1) to determine if molecular asymmetry and piezoelectricity are fundamental in the biologic activity of dusts, and (2) to determine the sources and forms of energy involved in the energy transferal mechanism

**PURPOSE 1**—To determine if molecular asymmetry and piezoelectricity are fundamental in the biologic activity of dusts

*General Statement*—Rats and rabbits were used in the experiments. The materials to be tested were first ground to desired size. Introduction of the material into the animal's body was done in different ways. In the early experiments the ground material was suspended in physiologic salt solution and sterilized. It was then injected into the peritoneal cavity with a modified syringe.

Because of difficulties due to plugging of the needle of the syringe, and because in some experiments it was desirable to use larger sized particles, this first method was modified. A small incision was made in the ventral abdominal wall, a small sterile funnel inserted, and dry sterile powder introduced through the funnel. The funnel was washed down with a small quantity of sterile physiologic salt solution. The quantity of material introduced in this way was always 100 milligrams. The incision was then closed with a skin clip. After closing the incision, the abdomen of the animal was gently massaged to distribute the material in the abdominal cavity.

In some animals the material was introduced into the trachea. The trachea was exposed and material forced down the tube toward the lungs with a modified syringe. Fifty milligrams was the quantity always introduced by this method.

In another group of experiments the sterile material was introduced by intravenous injection. Rabbits were used in all of these experiments. By one or more injections a total of 1 Gm. of material was injected into a vein of the ear.

For purposes of comparison, six animals were prepared with powdered quartz. The animals were sacrificed at varying intervals of time and microscopic sections prepared. The well known typical reaction to quartz is shown in Fig. 3.

*Wulfenite (Lead Molybdate), Crystal System—Tetragonal, Crystal Class—Tetrahedral*—This material was the major test substance used in preliminary experiments which were reported.<sup>4</sup> Unfortunately, the supply of material on hand became exhausted and material of identical x-ray diffraction pattern has been thus far unobtainable. The reason for the selection of this material and the description of the experimental results were given in the preliminary report.

Forty seven rats were prepared by injecting suspensions of wulfenite into the peritoneal cavity. The animals were sacrificed at different intervals from one to fourteen weeks. Four of the rats are still living. The average length of time the animals were allowed to live was thirty four days.

Wulfenite had caused extensive fibrogenesis in animals which were sacrificed after seven days. Large numbers of fibroblasts were accumulated around the particles of wulfenite. There was a tendency to form whorls. In some instances, younger connective tissue cells were present. These were irregular stellate cells surrounded by a homogenous intercellular substance. There was a tendency to the formation of collagenous fibers in animals in which the experiments were continued for a longer period of time. See Fig. 5.

Two of the rats were killed by exsanguination at six weeks. The blood was allowed to dry by evaporation and the residue was spectriographically analyzed. No lead or molybdenum was present. As the technique employed is sensitive to amounts of molybdenum as low as one part in a billion, and for lead, one part in one hundred million, it was apparent that solubility could not explain the reaction produced.

*Barium Titanate, Crystal System—Cubic, Crystal Class—Undetermined*—This synthetic material has recently excited much interest in the physical fields and the ceramic industry. It possesses a very high dielectric constant, and its piezoelectric coefficients are far in excess of those possessed by quartz.<sup>8</sup> The material used in this study was analyzed by an independent metallurgical laboratory and was found to contain less than 0.2 per cent silica. The material was insoluble in any pH conceivable in animal tissue. The material was received in a particle size below  $10\ \mu$  and no ball milling was necessary.

Twenty-five rats were injected intraperitoneally in the usual manner with suspensions of the material. These animals were sacrificed at periodic intervals from one to eight weeks with an average of twenty-four days' duration for the group.

*Results* By the end of the first week, the barium titanate depositions were noted to have become arranged in well-defined whorls, and a fibroblastic, relatively avascular reaction was already well defined. Giant cells and monocytes were not as numerous as with some of the other materials tested. As the time interval progressed, the whorls became increasingly fibrotic and collagenic. Based on experiences with quartz, it was observed that barium titanate was highly active in producing fibrogenesis in tissue. See Fig 10.

Four rats from the six-week duration group were killed by exsanguination. The blood obtained was allowed to dry and the residue subjected to spectriographic analysis. No barium or titanium lines were found. This analytic technique is qualitatively sensitive for barium or titanium when traces of either element are present in as low as one part in a billion for titanium and one part in one hundred million for barium. It is, therefore, safe to say that there was no solution of the barium titanate from the sites of deposition. These data are advanced to answer any "chemical solution" explanation for the fibrous reaction.

Nine rabbits were prepared by injection of a full gram of barium titanate in divided doses into the ear veins. This dose was accomplished in less than a week in all cases. These rabbits were sacrificed from two weeks to seven weeks after the completion of the preparation. Again, excessive fibroblastic reactions were noted at the site of barium titanate depositions. Interstitial pulmonary fibrosis, mesenteric fibrosis, and hepatic cirrhosis conforming to the distribution of the crystal were apparent in all animals.

It was observed that the reaction to this material in rabbits prepared intravenously was the same as that observed in rats.

*Tourmaline (Aluminum-Boron Silicate), Crystal System—Trigonal, Crystal Class—Hemimorphic Hemihedral*—This silicate is of historic interest be-

cause it is the substance in which the property of piezoelectricity was first described. It is of additional interest in that it does not have true right and left forms such as seen in quartz.

Eight white rats were prepared in the usual manner by intraperitoneal injection of a suspension of powdered tourmaline.

Four of the eight white rats were found dead in the fifth week of the experiment. Death had occurred over a week end and all were found on the same morning. They were all too far decomposed for histologic preparations. Gross fibrosis was present in all instances. Food and fresh water remained unconsumed and the cause of death was not determined. The experiment is being repeated in larger numbers to ascertain any possible significance of these deaths.

Two animals were killed at three weeks, and two at four weeks. Fibrotic reaction to the material was very excessive and intercellular collagen deposition was well developed by the end of the fourth week. See Figs 11, 13 and 15.

*Berlinite (Aluminum Orthophosphate), Crystal System—Trigonal, Crystal Class—Enantiomorphous Hemihedral*—Berlinite is aluminum orthophosphate which is physically and crystallographically isomeric with quartz. Our material was grown out of solution by the originators of a method developed to synthesize crystals for physical purposes. The material is soluble in acids, but insoluble in neutral solutions. The similarity in crystal structure between berlinite and quartz is illustrated by the striking similarity in their x-ray diffraction patterns. See Figs 1 and 2.

Eight white rats were injected intraperitoneally in the usual manner, using a ball milled powder of requisite particle size. These animals were sacrificed as follows: four at two weeks, two at three weeks, and two at five weeks.

At two weeks, a well developed fibrotic response was observed with considerably more monocyte and giant cell reaction than was seen with quartz or barium titanate. This monocyte response was noted in our studies whenever materials of greater relative solubility were used.

As time elapsed, the fibrous reaction advanced and became more mature. By five weeks, there was considerable intercellular collagen deposited. See Fig 4.

*Aluminum Phosphate (Reagent Grade)*—This material was selected originally for a control. It was determined to be amorphous by x-ray diffraction prior to preparation for injection. The material is insoluble in neutral solvents but is soluble in acid solvents.

Six rats were injected intraperitoneally in the usual manner with suspended aluminum phosphate. These animals were killed in pairs at three weeks, five weeks, and six weeks.

A spectacular fibroblastic reaction was observed at three weeks which increased with time, and by six weeks fibrous nodules as large as 1 cm in diameter were distributed throughout the peritoneum. Many giant cells were noted about the depositions of aluminum phosphate.

It was observed that, as time elapsed, fracture lines and facets appeared in the aluminum phosphate depositions which then resembled the beilinite deposits. The fibrous reactions were histologically similar to those seen with beilinite. This unexpected result from an intended control experiment will be considered in the discussion. See Figs 9, 12, 14, and 16.

*Cholesterol*—The crystal class of cholesterol is not certain, but, because of its known fibrotic activity when deposited in tissue in its solid crystal state, a series of experiments was included in this study. Commercial cholesterol in powdered form was x-ray diffracted and its crystal state was established.

Eight white rats were injected and were sacrificed at the following intervals: two at three weeks, two at four weeks, two at six weeks, and two at eight weeks. Several frozen sections of lesions were made in addition to the usual preparations, because xylol removed the cholesterol crystals leaving spicular spaces at the sites of previous crystal deposits.

The fibroblastic response was early and very active. Giant cell formation was prominent and similar to the reaction produced by aluminum phosphate. By eight weeks a mature nodule had developed. Inter cellular collagen formation was prominent. See Figs 6 and 8.

*Silicon Carbide (Carborundum), Crystal System—Hexagonal, Crystal Class—Holoedral*—This material was included as a control because it is not piezoelectric and is known to be nonfibrosive. Six rats were injected intraperitoneally in the usual manner. These animals were sacrificed in pairs at two, six, and eight weeks.

The reactions observed did not exceed simple foreign body encapsulation. See Fig 19.

*White Mica, Crystal System—Trichinic, Crystal Class—Prismatic*—Mica was included in this study as a control as it belongs to that group of silicates including talc and asbestos which produces variable biologic response.

Seven white rats were prepared intraperitoneally in the usual manner. Six animals were sacrificed at five weeks and one at six weeks.

Four of the animals were observed to show no reaction beyond simple foreign body encapsulation. Two showed a moderate fibrotic response, and the animal sacrificed at six weeks showed a well-developed reaction. See Fig 20.

*Fused Quartz and Ground Pyrex Glass*—Glass is a "super viscous fluid." Its viscosity prevents its becoming oriented molecularly into the preferred 'low energy' crystal state.

Because it lacks crystalline structure, it possesses no piezoelectric properties. With time, glass may reassume crystalline orientation as is well known to glass cutters who will accept the risk in cutting new glass, but refuse to cut old glass which often shatters along crystal lines.

A sample of quartz crystal was fused and thereafter ground to a powder. A sample of Pyrex glass also was ground to a powder. Both materials failed to show a crystal pattern when examined by x-ray diffraction. The resulting

powders reduced to requisite size were injected intraperitoneally in the usual manner. Three white rats were used for each material. One animal of each group was killed at two, six and eight weeks.

No reaction beyond simple foreign body encapsulation was observed. See Fig 17 and 18.

**PURPOSE 2**—To determine the sources and forms of energy involved in the energy transferral mechanism.

It has been pointed out that fibrotic activity of a dust may be correlated directly with the physical properties of the dust crystal. Further clarification of the mechanisms involved becomes pertinent. It is important to determine whether electric charge or mechanical distortion produce the most active biologic reaction. A theoretically complete separation of the direct and converse piezoelectric reaction and of the secondary thermal reactions is impossible, but when conditions are controlled one of the other reactions may be made to predominate. To this end several experimental procedures were devised. These are briefly described and separate reports will present details of procedure and results.

**1 Mixed Metal Experiment**—When two metals which occupy dissimilar positions in the electromotive series are placed in an electrolyte a battery producing a flow of direct current results. The voltage of such a battery is a factor of the connecting electrolyte and of the degree of electromotive dissimilarity in the metals considered. As the same technique is employed in the procedures to be described the factor of "connecting electrolyte" may be ignored as a relative constant.

Particles of electromotively separated metals introduced into tissues and so "connected" by electrolytic tissue fluid would produce direct currents. The bimetal dipoles in such a system might become distorted in their electrical axes to conform with a static or magnetic field but the *preponderate* activity would be a manifestation of electric potential.

The electric currents produced with mixed electromotively dissimilar metallic dusts in tissue would differ from those produced by a tissue deposition of stressed piezoelectric crystals because the current flow would be continuous and direct rather than intermittent and alternating. Furthermore the battery produced would "run down" with time and use while the crystal remains potent for the life of the animal. The similarity however is sufficient to warrant biologic study.

Aluminum ion and silver dusts were selected for study. Aluminum is strongly negative to silver and weakly negative to iron. Silver is strongly positive to aluminum and weakly positive to iron. The dusts were in each instance freshly suspended in weighed amounts before injection.

It was anticipated that strongly negative or positive dusts might form a battery when injected alone due to interaction with free metallic ions in tissue fluid. The single and mixed dust combinations studied are listed in

levels in accordance with the expected voltage (and biologic effect), the most active level being uppermost

First level	(Highest voltage)	Mixed Al and Ag
Intermediate level	Mixed Al and Fe Al alone	Mixed Ag and Fe Ag alone
Third level	(Little or no voltage)	Fe alone

In order to simplify presentation and avoid confusion, the results of "mixed metallic dust" experiments are reported separately. It may be stated here that galvanic currents stimulate fibrosis. See Fig 7. The rapidity and degree of fibrotic reaction is directly proportionate to the degree of electromotive dissimilarity between the metallic dusts selected for mixture. This is equivalent to stating that the reaction is proportionate to the amount of current produced. This is in agreement with observations made by others<sup>9</sup> working with large metallic plates inserted into tissue.

2 *Biologic Augmentation by Electromagnetic Fields*—Piezoelectric crystals of nearly uniform size possess fundamental frequencies for each of their several axes. At these frequencies, an alternating current produces a mechanical vibration with greatest efficiency. Similar crystal responses occur at several subharmonic and superharmonic alternating current frequencies.

It may be seen that there is a frequency range at which a piezoelectric dust of different size range may be expected to be energized. For some substances, as quartz, this range may be determined from known data. For other substances, an exciting frequency range may be determined by physical test means.

Several cages have been supplied with radio frequency energy in order to expose dust placed in a living tissue to various frequencies of energy fields. It was anticipated that, by so doing, a biologic response might be accelerated. This approach was, we believe, prematurely overemphasized in a preliminary report.<sup>4</sup>

This problem has been beset by many technical difficulties which are being resolved slowly. A detailed report will be submitted separately.

It may be stated that, in agreement with the preliminary report,<sup>4</sup> there is a definite increase in the rapidity and degree of fibrotic reaction to a fibrostatic dust when the prepared animal is exposed to oscillating fields of energy at a frequency known to produce piezoelectric responses in the same dust in vivo. This is supportive evidence that physical stress and motion are capable of stimulating fibrotic reactions.

Several other experiments testing the role of heat, motion, and electricity in fibrogenic reactions are in progress and will be reported separately.

#### SUMMARY OF EXPERIMENTS

1 Piezoelectric materials, including wulfenite, quartz, barium titanate, tourmaline, berilmite, and cholesterol, uniformly produce proliferative fibrous reactions when introduced as a finely divided dust into living tissue.

2 Nonpiezoelectric control dusts including ground glass and fused quartz, silicon carbide and non produce only an encapsulation reaction when introduced into living tissues

3 Micra produces variable responses in living tissue

4 Aluminum phosphate was used as an amorphous powder as a control dust. Crystal forms appeared in the tissue reaction and the reaction was notably fibrotic. Aluminum phosphate with water of crystallization occurs in forms which are crystal isomers of quartz, tridymite, and cristobalite

5 Galvanic currents produced by mixtures of electromotively dissimilar dusts produce active fibrogenesis

6 Fibrogenesis is accelerated when an animal prepared with a piezoelectric dust is kept in a concentrated electromagnetic field of appropriate frequency

#### DISCUSSION

The present experiments were devised to determine whether substances possessing proper asymmetrical molecular space orientation and satisfying the other postulated properties for fibrogenic activity would behave in the manner expected. The results have clearly supported the concept and indicate that the phenomenon of piezoelectricity does exert biologic influence. Piezoelectricity has been defined earlier but it should be added here that, in addition to the direct and converse piezoelectric effects there are many related secondary effects. More study is needed to establish the forms and magnitudes of the energy sources occurring in nature and their biologic influence when converted by piezoelectricity. The piezoelectric property allows a theoretical transference of energy states in any direction between mechanical, electric, and thermal states.

There is a paucity of biologic and physical data from which one might define the physical behavior of minute solid deposits within tissue. On the other hand, the theory presented explains many previously unreconcilable observations and, in some instances is actually strengthened by these observations. The "chemical solution" theory of silicosis has presented many unsolved objections in addition to the important fact that fibrous tissue presents a poor barrier to substances in solution. The degree of solubility is not correlated with pathogenicity. The influence of the size of the particles has too sharp an end point to be a function of surface area alone. A critical number of particles is necessary to produce progressive fibrosis. A period of time is often observed between the termination of exposure and the onset of fibrosis, and, in clinical silicosis this interval often amounts to years. There has been no demonstration of either dissolution of crystals or actual solution in the areas of local involvement beyond that level of solution present in remote and uninvolved areas of the organism. All of these observations are irreconcilable with the solubility theory yet are either consistent with or strengthening to the theory being discussed. This present theory embodies the concept that naturally occurring sources of force are present in discon-

tinuous "bursts" of proper form and magnitude to effect intermittent piezo electric responses in a proper "receptor," which responses constitute the fibrogenic stimulant

Many problems present themselves for future clarification. The known fibrogenic activity of several symmetrical crystals (talc, asbestos, etc.) is troublesome. This problem is presently under investigation in the light of "unstable crystal symmetry" and will be reported in more detail later. King, Gulchist, and Rae<sup>11</sup> provided a clue when they reported that several benign shales and sericites became biologically active when treated with HCl. Guided by this observation, several samples of talc, asbestos, and mica have been similarly treated with chemically pure HCl and quantitative chemical determinations were made. As much as 4 per cent of the sample weight is lost, and this weight is recoverable in the HCl in the form of the chlorides of Al, Mg, Fe, Ca, Na, and other metals. When the residual material was subjected to x-ray diffraction, the patterns showed qualitative and quantitative changes by comparison with the original substance patterns. Further study in this regard with animal experiments will be forthcoming, but a statement is made at this point to emphasize that the material used in preparation of an animal may change to a pathogenic form after introduction into the animal.

Another problem requiring clarification is the observation that amorphous opal and our amorphous aluminum phosphate are both fibrogenic. This may be explained by the known tendency of amorphous material to crystallize when conditions are right. Amorphous aluminum is known to become crystalline in a quartz class when heated for purposes of sterilization.<sup>12</sup> The crystal state represents the preferred low energy state, and the amorphous state is maintained by a viscosity which precludes molecular reorientation. If the physical environment is proper, the amorphous material may return to the preferred crystal state. Diatomaceous earth is biologically inactive, but, after calcining at high temperatures, a diffraction pattern of cristobalite arrangement appears and the "new" dust develops a pathogenicity in keeping with its new crystal structure.<sup>13</sup> A similar perversion might occur in the animal tissue. This matter is under study with the hope that materials recovered from the fibrotic reaction sites may be subjected to x-ray diffraction for crystal orientation. A second possible explanation for the activity of amorphous materials is that piezoelectric properties may operate biologically at a molecular or unit cell level. This interpretation is not consistent with our experiences using ground fused (amorphous) quartz, which was benign by test. A third explanation is that electrical orientation might occur without true crystallization, and "electrets" with piezoelectric behavior might result. This has been accomplished when asymmetrical molecules are made to become electrically oriented without developing true crystal structure.<sup>14</sup> This consideration is presently under experimental test.

It also has been observed that one of the dusts (chalcopyrite), classified as benign in the studies of others,<sup>15</sup> belonged to an asymmetrical crystal class. Further consideration revealed that this dust was electrically conductive and

reactive piezoelectrically by test.<sup>7</sup> This exceptional instance stimulates speculation as to a functional explanation of the effect of aluminum therapy and of iron hydroxide coating in modifying the fibrotic reaction to quartz. Polarity and, hence, piezoelectric activity might be "short circuited" by coating the particle with a thin skin of material of higher electric conductivity than the crystal itself or the tissue fluid around the crystal.

The piezoelectric mechanism requires an energy source, and several likely sources have been presented. Many observations have suggested that there are environmental factors influencing the incidence and character of disease states which cannot be explained in conventional terms. It is possible that environmental fluids of electromagnetic force can be of pathologic importance through the piezoelectric mechanism. If this be true a description of a biologic environment will remain incomplete until it includes a statement covering the frequency and intensity of force fields surrounding the host. This subject will be considered in more detail in subsequent studies.

Fibrous tissue makes its contribution to biologic economy by supplying physically supportive elements. When fibrous replacement represents the preponderant reaction to an injury one should suspect that injury to be of a physical order, because it is this order of stimulation that fibrous tissue is functionally qualified to resist.

Within biologic variation fibrous tissue reactions are more "specific" to the site and degree of involvement than to the chemical nature of the fibrogenic material. Quartz, the tuberculous phospholipid and cholesterol have been shown to exert a biologic influence which is both interchangeable and 'symbiotically' additive when equal distribution is effected in similar tissue sites. This observation alone strongly suggests a common mechanistic relationship between the substances.

A mechanism has been demonstrated which exerts potent mitogenic influence when it acts in tissues. It is therefore important that those physiologic and pathologic states which are characterized by rapid proliferation of cells be restudied in the light of this mechanism. It is impossible to forecast where the mechanism will prove important. There are several biologic phenomena which seem specially suggestive. A classification of the problems under consideration and the basis for selection is presented. This classification is purest speculation and no commitments beyond the conclusions of this paper are intended. The classification is presented for the sole purpose of stimulating thought and of inviting collaboration and expansion.

### *Classification of Topics Suggesting Piezoelectric Mechanisms —*

#### *A Physiology*

- 1 Normal growth and differentiation (growth stimulating steroids)
- 2 Hormonal reactions as lactation and menstruation (steroids in general have very asymmetrical molecules)

#### *B Pathologic States*

- 1 Pathologic states at the site of strong and intermittent mechanical stress vectors
  - (a) Heart and major vessels (Aschoff bodies atherosclerosis)

- (b) Joints (Rheumatoid arthritis and allied states)
- (c) Thorax with cough and respiration (Pulmonary fibrosis in tuberculosis, silicosis, etc)
- 2 Situations where minute manifestations of potential could occur
  - (a) Hypersensitivity If the attractive charges of the antigen and the antibody were not dissipated at the point of contact when the immune body is formed, a minute dipole similar to that produced in the bimetal experiment would result (Overlaps with 1(a) for Aschoff bodies and with 1(b) in rheumatoid arthritis)
- 3 Situation in which there is an increase in metabolic products of asymmetrical molecular structure This includes both host and bacterial metabolic products
  - (a) Hypercholesterol and lipemic states (Overlaps with 1(a) in atherosclerosis and vascular disease)
  - (b) Tuberculous phospholipid (Overlaps with 1(c) in fibroid tuberculosis)
  - (c) Malignant change where associated with disturbed sterol metabolism and with large dose hormone therapy (Cancer of breast, prostate, testes, ovaries, and perhaps other neoplasms as well)
- 4 Pathologic lesions which conform architecturally with the equations of force such as Boeck's sarcoid, the other granulomata

It is again emphasized that this outline is for experimental organization and is not to be construed in any other light. It will be noted that all the classes outlined share in common the feature of cellular proliferation. In addition to cellular proliferation, each class possesses one or more of the mechanistic essentials of a piezoelectric reaction: (1) An acceptable energy source—heading B, 1. (2) An acceptable molecular receptor in excessive concentration—headings A, 1, A, 2, B, 2, B, 3 (a), B, 3 (b), B, 3 (c). (3) A manifestation of electrical potential—heading B, 2 (a).

B, 2 (a) classification is particularly speculative. This class is considered worth study as presented because of some recent highly significant observations. When a suspension of very finely divided biologically active dust is injected into the heart of a guinea pig, a "quick death" within a matter of minutes results. The death mechanism is clinically and pathologically indistinguishable from the "protein" death in guinea pigs that have been sensitized and shocked anaphylactically. This death reaction does not occur when benign dusts are similarly injected or when aluminum-hydroxide is added to the active dust suspension. We are indebted to Dr. Arthur Voisard for informing us of his remarkable experiment. It is felt that if an immune body failed to lose the attractive opposite charges of its antigen and antibody components due to abnormal electrical resistance at the area of contact, this immune body would become a minute dipole similar to the bimetal dipole discussed earlier and similar to the electric polarizations which appear on the surface of piezoelectric crystals. Again, the dampening effect of the aluminum hydroxide might be explained by the formation of a thin electrically neutralizing skin over the surface of the dust.

#### CONCLUSIONS

1 The ability of foreign materials to produce fibrogenesis is correlated with their crystalline structure.

2 Those tested amorphous materials and materials whose crystalline state possesses a central point of molecular symmetry (symmetrical crystals) are nonfibrogenic

3 Those tested crystals which do not possess a central point of symmetry (asymmetrical crystals) and possess piezoelectric properties are fibrogenic

4 Several materials previously untested biologically, selected for their physical properties, were tested and shown to be fibrogenic

5 Fibrous tissue reactions are considered to be stimulated by releases of energy in mechanical or electrical states within tissue

## TISSUE RESPONSES TO PHYSICAL FORCES

### III THE ABILITY OF GALVANIC CURRENT FLOW TO STIMULATE FIBROGENESIS

SILAS M. EVANS, M.D., AND WALTER ZEIT, PH.D.  
MILWAUKEE, WIS.

#### INTRODUCTION

A CONCEPT has been presented in earlier reports<sup>1,2</sup> which depicts fibrous tissue reactions as stimulated by and protective against releases of physical force. These earlier reports discuss a *modus operandi* whereby energy is transformed from a biologically noninfluential to a biologically active state. It was stated that separate reports would deal with the fibrogenic potential of individual energy states. As piezoelectricity is a property of certain materials to transform energy in any direction between motion, heat, and electricity, each of these energy states requires separate consideration.<sup>1,2</sup> When a piezoelectric crystal, e.g., quartz, which is deposited in tissues becomes squeezed by cough, strain, muscular activity, arterial pulsation, or any other physiologic means, it is capable of producing a current of electricity. The present report deals with the effect of such currents in tissue.

When two metals with dissimilar electromotive levels are connected by an electrolyte, they produce a flow of direct current. The characteristics of such a current differ from the current characteristics of a stressed piezoelectric crystal in the following manners:

#### Bimetal Battery Current

- 1 Current flow in one direction
- 2 Uninterrupted current flow
- 3 Limited duration—current will stop when the battery is "run down"

#### Piezoelectric Crystal Currents

- 1 Current flow in one direction while the crystal is stressed and in opposite direction when the stress is relieved
- 2 Interrupted current flow occurring only during stress and relief of stress
- 3 Unlimited duration as the crystal does not liberate energy but transforms energy from a source outside itself

In spite of these differences in current characteristics, there is sufficient similarity to make experimental consideration important.

In a bimetal electromotive battery, the voltage produced depends on the degree of electromotive dissimilarity of the metals and the resistance of the electrolyte (Ohm's law). As a similar technique is employed in similar animals, the factor of electrolyte resistance may be disregarded as a constant.

The importance of selecting identical metals which are electromotively neutral with tissues for screws and plates in orthopedic surgery has been emphasized by others.<sup>3</sup> It also has been shown that single metals may interact with the tissues in which they are implanted, resulting in current flow. The

From the Departments of Medicine and Anatomy, Marquette University School of Medicine.  
Received for publication Feb. 1, 1949.

degree of fibrous tissue reaction has been shown to be proportionate to the amount of current produced.<sup>1</sup> These principles appear to be well established with large implants such as plates and screws. Heretofore, no data have been available describing the behavior of dust size bimetal deposits in tissues.

Silver, aluminum, and iron powders were selected for study. Aluminum is strongly positive electrically to silver and moderately positive to iron. Silver is strongly negative to aluminum and moderately negative to iron. Iron occupies a mid position electrically and is near the electromotive position of tissue fluids. The experimental procedure employed all three metallic dusts individually, as well as the three combinations of two mixed dusts. It is theoretically consistent to state that different levels of voltages were experimentally produced in tissue. The purpose of the experiment was to determine if the magnitude of the fibrotic response was proportionate to the voltage produced.

#### Theoretical Voltage Table

Mixed Ag and Al	Highest voltage
Ag alone Al alone	Intermediate voltage
Ag and Fe Al and Fe	
Fe alone	Minimal or no voltage

#### MATERIALS

- Dusts 1 Aluminum metal dust  
2 Precipitated silver dust  
3 Iron powder

Animals Thirty four adult white rats were used in the experiment

#### METHOD

*Intraperitoneal Preparations*—One hundred milligrams of metallic dust were used in each experiment. This amount was either entirely of one dust, or, where two dusts were mixed, 50 mg of each fraction were used. All dusts were mixed immediately before injecting intraperitoneally into an anesthetized rat. The abdomen of the rat was then massaged to distribute the dust.

*Intratracheal Preparations*—The trachea of the anesthetized rat was exposed and the suspension of dust was injected into the trachea. Ten milligrams of a single dust or 5 mg each of mixed dusts were injected in each instance.

*Aluminum*—Three rats were prepared by simultaneous intraperitoneal and intratracheal injection. These rats were sacrificed at two, four, and six weeks.

*Iron*—Six rats were prepared intraperitoneally but not intratracheally. These animals were sacrificed as follows: one at four weeks, one at eight weeks, two at twelve weeks, and two at sixteen weeks.

*Silver*—Three rats were prepared intraperitoneally and intratracheally. They were sacrificed at one, three, and five weeks.

*Silver and Aluminum*—Six rats were prepared intratracheally and intraperitoneally. These animals were sacrificed at one, two, three, four, five, and six weeks.

*Silver and Iron*—Seven rats were prepared intraperitoneally but not intratracheally. These were sacrificed as follows: two at three weeks, two at four weeks, one at five weeks, and two at eight weeks.

*Aluminum and Iron*—Nine rats were prepared intraperitoneally but not intratracheally. These were sacrificed as follows: one at two weeks, two at four weeks, two at six weeks, two at eight weeks, and two at twelve weeks.

#### RESULTS

The results are described under four headings as determined by the magnitude of the reactions observed.

Reactions in the white rat (*Mus norvegicus*) to the highest theoretical voltage mixed silver and aluminum dust preparations

Fig 1—Reaction in the lung produced in two weeks ( $\times 400$ )

Fig 2—Intraperitoneal nodule produced in six weeks ( $\times 200$ )

Fig 3—Intraperitoneal nodule produced in two weeks ( $\times 400$ )

Reactions in the white rat to the second highest theoretical voltage, aluminum dust only

Fig 4—Intraperitoneal nodule produced in six weeks ( $\times 200$ )

Fig 5—Nodule on the surface of the liver produced in six and one half weeks ( $\times 200$ )

Fig 6—Nodules produced in the lung in six and one half weeks ( $\times 200$ )

Reactions in the white rat (*Mus norvegicus*) to the highest theoretical voltage, mixed silver and aluminum dust preparations

Fig 1—Reaction in the lung produced in two weeks (×400)

Fig 2—Intraperitoneal nodule produced in six weeks (×200)

Fig 3—Intraperitoneal nodule produced in two weeks (×400)

*II Silver Alone, Aluminum Alone*—The reactions to these dusts were similar histologically to the reactions to the mixed aluminum and silver preparations. The reactions were not as grossly extensive. Dense, collagenous, avascular, fibrous whorls were slower in formation. The lesions produced were considered qualitatively similar to those produced by mixed aluminum and silver, but quantitatively less excessive and slower in development. See Figs 4, 5, and 6.

*III Silver and Iron, Aluminum and Iron*—These preparations produced a reaction with a less notable proliferation of fibroblasts and with minimal deposition of collagen. There was more vascularity and less extensive gross reaction than was seen in the preceding groups. Of particular interest was the microscopic appearance of a 'run down' electromotive battery. The two metals could be distinguished microscopically, and one metal was observed to "plate" the other.

*IV Iron Alone*—In this group the reactions were observed to be no more proliferative than is seen in simple foreign encapsulation.

#### DISCUSSION

The results obtained justify the conclusion that the magnitude of the reactions produced by electromotive currents is proportionate to the voltage theoretically developed. Work is in progress to ascertain if the dielectric properties of mature fibrous tissue as compared with other tissues of the body, qualify fibrous tissue as relatively insulative and hence protective against electrical stimuli.

In these experiments aluminum or silver alone appeared more reactive than aluminum and iron or silver and iron. This is misleading. Iron is relatively near to animal tissue electromotively. The iron, therefore contributed nothing to the reactions which the surrounding tissue alone would not have supplied. It should be noted that, in the unmixed aluminum and the unmixed silver preparations, 100 mg were used intraperitoneally whereas in the aluminum and iron, and silver and iron mixed experiments only 50 mg of aluminum or silver were used. The factor of dosage therefore is obviously uncontrolled in these two groups.

The significance of these observations in the general problem of fibrotic reactions to disease has been discussed in earlier papers.<sup>1</sup>

#### CONCLUSIONS

- 1 Currents of electricity produced electromotively in tissues are capable of stimulating fibrotic reactions.
- 2 The magnitude of the reaction is proportionate to the voltage generated.

# QUANTITATIVE SPECTROGRAPHIC ANALYSIS OF BLOOD AND TISSUE FLUIDS

ROBERT M. STECHER, M.D., HOWARD M. BEDELL, B.S., AND IRENE LEVIS, PH.D.  
CLEVELAND, OHIO

THE present study is limited to the quantitative determination of metallic elements in biologic material by the emission spectriograph using electrical excitation. Electrical excitation emission spectroscopy is to be distinguished from emission flame spectroscopy and absorption spectroscopy. Emission flame spectroscopy is limited in general to analysis of those elements having low excitation potentials such as the alkali metals. In flame spectroscopy the elements are excited to emit light by introducing the sample into a gas flame where the temperature is in the range of  $1,500^{\circ}$  to  $3,000^{\circ}$  C. By using electrical excitation where the sample is burned in an electric arc, temperatures of  $5,000^{\circ}$  to  $8,000^{\circ}$  C. are obtained. It is possible, therefore, to excite even those elements having very high excitation potentials. Absorption spectroscopy lends itself best to the analysis of organic compounds in solution and is accomplished by passing light of all wave lengths through the sample and studying the absorption pattern obtained.

## THEORETICAL CONSIDERATIONS

Every element, when burned, produces radiations of monochromatic light which are specific. When such radiations are dispersed in a spectriograph and recorded on a photographic film they can be positively identified both qualitatively and quantitatively. The intensity of light emitted by any element during the burning is proportional to the amount of that element present. These are the principles upon which spectriographic analysis is based. In actual practice the amount of any element present in a sample is determined by measuring, with a microphotometer, the blackness of the photographic images of the specific spectral lines produced. A quantitative analysis of a sample for the metallic elements is made by comparing the spectrum of the sample with the spectrum of a known standard. The theoretical requirement of a standard is that it shall be identical with the sample in both physical structure and in general chemical composition. It is obvious that it is impossible to synthesize a real blood of known composition. The first necessity in the spectriographic analysis of blood becomes, therefore, that of converting the sample to a form which may be duplicated by a synthetic standard of known composition. This is best done by destroying the organic constituents by acid digestion or by low temperature dry ashing which also fixes the metallic elements as inorganic salts or oxides.

The authors are indebted to Dr. Howard T. Karsner for his advice and encouragement

Received for publication Nov. 30, 1948

The amount of any element present is determined by measuring the blackness of the photographic image produced. This is done with a microphotometer which determines by means of a photoelectric cell and galvanometer, the percent of light transmitted through the line image. This transmittancy is inversely proportional to the intensity of light producing the image on the photographic plate according to Fig 1.

Fig 1—Characteristic curve of photographic emulsion

If the overall intensity of spectra could be reproduced accurately from sample to sample intensity of an element line could be plotted directly against the element concentration. This is not the case however so a correction for small variations in the intensity of spectra is made by use of the internal standard method which consists of adding a weighed amount of a foreign element to a measured amount of sample. The intensity of light emitted by the element used as internal standard is then accepted as a quantitative measure of the sample consumed or recorded. The element used for an internal standard must be chosen with care. It must be an element available in pure form, be chemically and spectrographically compatible with all elements to be assayed and have a simple spectrum which does not interfere with the sensitive lines of the trace elements.

The concentration of the unknown element is proportional to the ratio of the light emitted by that element to the light emitted by the internal standard. The ratio of light from the unknown element to light from the internal

# QUANTITATIVE SPECTROGRAPHIC ANALYSIS OF BLOOD AND TISSUE FLUIDS

ROBERT M. STECHER, M.D., HOWARD M. BEDELL, B.S., AND IRENE LEVIS, PH.D.  
CLEVELAND, OHIO

THE present study is limited to the quantitative determination of metallic elements in biologic material by the emission spectriograph using electrical excitation. Electrical excitation emission spectroscopy is to be distinguished from emission flame spectroscopy and absorption spectroscopy. Emission flame spectroscopy is limited in general to analysis of those elements having low excitation potentials such as the alkali metals. In flame spectroscopy the elements are excited to emit light by introducing the sample into a gas flame where the temperature is in the range of  $1,500^{\circ}$  to  $3,000^{\circ}$  C. By using electrical excitation where the sample is burned in an electric arc, temperatures of  $5,000^{\circ}$  to  $8,000^{\circ}$  C. are obtained. It is possible, therefore, to excite even those elements having very high excitation potentials. Absorption spectroscopy lends itself best to the analysis of organic compounds in solution and is accomplished by passing light of all wave lengths through the sample and studying the absorption pattern obtained.

## THEORETICAL CONSIDERATIONS

Every element, when burned, produces radiations of monochromatic light which are specific. When such radiations are dispersed in a spectriograph and recorded on a photographic film they can be positively identified both qualitatively and quantitatively. The intensity of light emitted by any element during the burning is proportional to the amount of that element present. These are the principles upon which spectriographic analysis is based. In actual practice the amount of any element present in a sample is determined by measuring, with a microphotometer, the blackness of the photographic images of the specific spectral lines produced. A quantitative analysis of a sample for the metallic elements is made by comparing the spectrum of the sample with the spectrum of a known standard. The theoretical requirement of a standard is that it shall be identical with the sample in both physical structure and in general chemical composition. It is obvious that it is impossible to synthesize a real blood of known composition. The first necessity in the spectriographic analysis of blood becomes, therefore, that of converting the sample to a form which may be duplicated by a synthetic standard of known composition. This is best done by destroying the organic constituents by acid digestion or by low-temperature dry ashing which also fixes the metallic elements as inorganic salts or oxides.

standard is called the intensity ratio. Actual computation of the results is done by applying the intensity ratio of the sample to the analytic working curves. Analytic working curves are established by burning a set of three or more synthetic standards containing the internal standard and known amounts of the elements to be analyzed in high, medium, and low concentrations within the ranges expected. Such synthetic samples should be made to approximate the nominal composition for all elements of the material to be analyzed even though only one element is to be determined. Analytic

Fig. 4—Shape of graphite electrode used

working curves have to be determined separately for each spectriograph and redetermined from time to time for the same instruments. The analytic working curves for lead (Pb), iron (Fe), magnesium (Mg) and sodium (Na) in blood used in these studies are shown in Fig. 2, and for lead, magnesium, and phosphorus (P) in urine in Fig. 3.

#### PROCEDURE

The first work and that from which the data and analytic curves in this paper were obtained was based on variations of a wet ashing technique, using a mixture of perchloric and nitric acids to destroy the organic material in the blood. The best results by the acid digestion method were obtained by digesting 5 cc of blood in 15 cc of  $\text{HClO}_4$  plus  $\text{HNO}_3$ , the acids being in the ratio of 2:1. The mixture of blood and acids was taken to dryness and the residue picked up in 5 cc of nitric acid solution containing 4 Gm of cadmium acetate per 100 cc of acid. Bismuth was used in place of cadmium as an internal standard with good success particularly in the determination of lead. Synthetic standards simulating the mineral content of blood are made by dissolving pure salts in a dilute nitric acid solution.

After digestion, 0.02 or 0.05 c.c. of sample, depending on sensitivity required, is then pipetted into the cup of a pure graphite electrode. The electrode used is of the type shown in Fig. 4. The sample is dried in the cup of the electrode by the heat of an infrared lamp. Best results are obtained by using electrodes in which a drop of pure liquid petrolatum has been allowed to soak in and air dry before the sample or the standard is put into the cup. This prevents the sample solution from soaking deeply into the graphite and gives a deposit of salts in the cup on drying. The sample is then burned in a direct current arc with a current of 15 amperes. A burning time of about ten seconds is sufficient to completely volatilize the sample when the oil-treated cup is used. The synthetic standard is burned in juxtaposition on the same photographic film to facilitate quantitative determinations.

A microtechnique was developed using a sample of only 0.02 c.c. of blood obtained either by a skin puncture or from a sample of heparinized blood taken by venepuncture. The sample is measured in a standard Sahli hemocytometer and is delivered into the cup of a pure graphite electrode. The sample is covered with the same amount of concentrated perchloric acid to which 4 Gm. of cadmium acetate per 100 c.c. have been added as internal standard. Heat is applied gently to the electrode with an infrared lamp for about thirty minutes until the specimen is digested. The sample is burned in a direct current arc as before. Again a synthetic standard sample is burned and recorded in juxtaposition on the same photographic film. Some difficulty was encountered because of the rapid reaction of the blood with the perchloric acid and also because of the difference in the absorption of the blood and of the synthetic standard solutions into the graphite cups and the resulting different rates of volatilization into the arc. Reasonable duplication of results was obtained under carefully controlled conditions.

A dry ashing technique was developed and tried which gives excellent results with minimum difficulty. A small piece of ashless filter pad is packed into the cup of the electrode. Samples of both the blood and the synthetic standard are prepared in identical fashion by pipetting 0.02 c.c. into the pad, then 0.02 c.c. of cadmium acetate solution is added. The electrodes are placed in an oven controlled at 850° F. maximum. Ashing is complete in about one to one and one-half hours. An excessive ashing time may cause the loss of any of the more volatile elements. A small deposit of mineral ash is left in the bottom of each electrode and there should be no absorption of any of the minerals into the graphite of the electrodes. The deposit is rather light and fluffy, so that to prevent loss at the initiation of the arc a drop of  $\text{HNO}_3$  should be put in each cup. The sample is caked and some of the minerals are dissolved and carried into the surface of the graphite. A small amount of penetration is not objectionable provided that it is uniform with both the unknown and the standard solutions. The electrodes are then burned in the direct current arc as before.

Another treatment of the sample after ashing which shows good promise, particularly in stabilizing the arc and enhancing sensitivity, is that of packing lithium carbonate into the cup on the ash. The ash is fused with the lithium compound on heating in the arc and the burning characteristics are those of the lithium compound. The cadmium is still used as the internal standard and an exact measurement of the lithium is not required. This method is very similar to that reported by Myers<sup>1</sup> and others in the analysis of leaves and other plant tissue for both major and trace mineral elements.

After burning the samples in any of the described techniques, the film or plate is developed under rigidly controlled conditions as to temperature and time, and the measurements of the line intensities are made with the microphotometer. Manufacturers' specifications for film processing are followed.

Fig 5—Schematic diagram of microphotometer. A Constant light source B line image on films C photocell and slit D variable resistance E galvanometer F meter scale  $I_0$  original light intensity  $I$  transmitted light intensity  $T$  transmission

#### CALCULATIONS

The method by which the ratio of the intensities of two spectral lines is determined is as follows

The transmittancy of the line image on the photographic plate is determined by means of the microphotometer as illustrated in Fig 5 which shows a schematic diagram of the microphotometer

The galvanometer circuit is adjusted to read zero deflection when no light strikes the photocell and to read 100 when the light passes through clear film. Then the reading obtained when a line image is interposed between the light source and the photocell is called per cent transmission ( $T$ ). It is obvious that the blacker the line on the film, the lower the reading ( $T$ ) which will be obtained. This in turn indicates a stronger intensity of light emitted by the element under study which produced the image. The relationship of ( $T$ ) with respect to relative intensity ( $I$ ) of light emitted by the elementary sample is shown in Fig 1. If for example as shown in Fig 1, in the analysis of blood for iron the values for  $T$  are  $T_{Fe} = 40$  and  $T_{Cd} = 30$  then  $I_{Fe}/I_{Cd} = 0.92/1.28 = 0.72$ . From Fig 2 the concentration of iron would be found to be 27 mg/100 cc of whole blood.

TABLE I COMPARISON OF CHEMICAL AND SPECTROGRAPHIC ANALYSIS OF 25 FE DETERMINATIONS OF WHOLE BLOOD IN MG PER 100 CC

SPECTROGRAPHIC	CHEMICAL	DIFFERENCE
34	35.2	+1.2
31.2	37.8	+3.6

## RESULTS

Observations were first made on iron because it was easy to check spectrographic results by chemical methods. A series of determinations on twenty-five different samples of blood chosen at random from the medical service at City Hospital is shown in Table I. The results are arranged in ascending order of magnitude as determined by this spectrographic method. The values ranged from 34.0 to 55.0 mg per 100 cubic centimeters. The iron content was determined chemically. The results obtained by both methods were in essential agreement. The actual deviation of the spectrographic method from the chemical method ranged from +5.7 to -3.1 mg per 100 cubic centimeters. The average difference was +1.64. These deviations were from +12 per cent to -8 per cent, with an average of +5 per cent. The standard deviation for the series was 6.06 per cent of the amount present.

After showing that the iron determinations obtained spectrographically compared favorably with those obtained by conventional chemical tests, recovery and reproducibility studies were made. Reproducibility of iron is

TABLE II REPRODUCIBILITY DETERMINATIONS ON OX BLOOD WITH ADDED MINERALS (MG PER 100 CC)

	Fe	Na	Mg	Pb
Sample 1	42	320	3.9	9
	42	340	4.1	11
Sample 2	76	410	9.6	5
	80	385	8.6	5
	80	380	8.0	6

shown in Table II. Sample 1 is that of a sample in the low normal range of concentration, whereas Sample 2 is a normal blood to which none has been added. The non-determinations checked within 5 per cent in the three determinations on the second sample and were identical for the duplicate runs of Sample 1.

Observations on sodium are shown in Table II. Good reproducibility within 7 per cent of the amount present was obtained on both samples. Sample 2 demonstrates good recovery, because it is Sample 1 to which 50 mg of Na per 100 cc were added. Results for Pb shown in Table II and Table III demonstrate both recovery and reproducibility. All samples were normal blood to which calculated amount of Pb were added to give 0.05, 0.1, 0.2, 0.4, 0.5, and 1.0 mg per 100 cubic centimeters. Correction was made for the original Pb in the blood.

TABLE III THE RECOVERY OF LEAD ADDED TO WHOLE BLOOD (MG PER 100 CC)

Tests were equally satisfactory for magnesium.

Any of the body fluids which may be measured onto the filter pad in the electrode may be analyzed in exactly the same manner. Standards prepared to have mineral concentration simulating those normally present in the body fluid under study are required for accurate quantitative analysis.

#### EQUIPMENT

These studies were started on an original grating spectriograph having high resolving power and high dispersion. Such an elaborate instrument is not necessary because subsequent experience proved that equally accurate results were obtained with a less expensive instrument (Jurell Ash 3 meter replica grating Wadsworth mount). The smaller instrument because of its higher wave length coverage and increased speed, is more desirable for this work in some respects than the larger instrument. The small instrument covers in one exposure the entire spectral range necessary to determine all the elements from potassium at 7800 Å° in the high visible range to phosphorus at 2500 Å° in the low ultraviolet.

## SUMMARY

Emission spectriography offers a convenient, accurate, and rapid method of making simultaneous quantitative determinations for several elements in one sample. Although the method has so far been tested only for iron, sodium, potassium, magnesium, calcium, and lead, we are confident that it can be readily adapted to many more.

# THE USE OF THE EMISSION SPECTROGRAPH FOR THE QUANTITATIVE DETERMINATION OF Na, K, Ca, Mg, AND Fe IN PLASMA AND URINE

A J BOYLE, M D, T WHITEHEAD, M S, L J BIRD, PH D,

**E**MISSION spectrography is a common industrial procedure for the analysis of alloys. Each element is recognized by the characteristic spectrum emitted when it is subjected to high temperatures in an electric arc or spark. The spectrum is dispersed by means of a grating or prism which separates the lines to a fraction of an angstrom. The spectrum is photographed on calibrated plate or film.<sup>1, 2</sup> The density of the spectral lines is related to the concentration of the element. Quantitation is obtained by the incorporation of a known amount of a foreign element which serves as an internal standard.<sup>3</sup> By photoelectric comparison of the densities of the spectral lines of the element being determined and the internal standard the concentration may be obtained.

Numerous methods for the analysis of solids and liquids, using both arc and spark sources, have been described by Brode.<sup>4</sup> The customary, but time consuming, procedure for the analysis of solutions is to evaporate to dryness in a craterized carbon electrode before ignition. Solutions also have been analyzed by direct introduction through a capillary into the electric source,<sup>5</sup> but in our experience this method has been unsatisfactory. The special feature of the method reported in this communication is the employment of a rotating disk electrode, or rotode, one section of which is partially immersed in the prepared biologic fluid. As the disk rotates the sample is picked up on the surface of the electrode and brought under the influence of high voltage spark excitation.

## PREPARATION OF SAMPLE

The purpose of sample preparation is threefold: (1) destruction of interfering organic matter, (2) incorporation of a known amount of a foreign element as an internal standard, (3) adjustment of final volume to make spectral lines of optimal intensity.

Prior destruction of plasma and urinary protein is necessary to prevent coagulation during sparking and consequent irregularity in cation vaporization. Direct treatment of the plasma with warm tetraethyl ammonium hydroxide is the simplest method for destruction of protein and produces a sample suitable for spectrographic analysis of Na, Ca, Mg and Fe. However, the ammonium ion impairs sensitivity to such an extent that the intensity of the potassium lines is reduced below a point where they can be read with accuracy. A 2:1 nitric perchloric acid mixture is adequate for the destruction of protein and

From the Departments of Chemistry and Medicine, Wayne University.

Received for publication Nov. 9, 1948.

nonprotein nitrogenous compounds in the plasma and produces a sample suitable for the determination of K as well as Na, Ca, Mg, and Fe. To effectively destroy the large amounts of urea in urinary samples, it is necessary to use hydrochloric acid in addition to the nitric-perchloric mixture.

Lithium, cadmium, nickel, and copper were tried as internal standards and lithium was found to be most suitable. In the event that lithium is used clinically as a salt substitute, it will be necessary to change the internal standard. Either cesium or rubidium should be satisfactory.

*Plasma*—Samples must be collected in glass stoppered containers to prevent the adsorption of cations by cork or contamination by rubber stoppers. Four cubic centimeters of heparinized plasma are pipetted into a 250 ml beaker, to which are added 15 cc of 2:1 nitric-perchloric acid mixture\* and 30 cc of a 0.3 Gm per cent lithium chloride solution. The lithium serves as an internal standard. The beaker is covered with a watch glass and the solution is permitted to evaporate to incipient dryness. Five cubic centimeters of distilled water are added to the cooled beaker and the contents swirled until the solution is complete. This completes the preparation of the sample for spectriographic analysis.

*Urine*—To 100 cc of urine in a 250 ml beaker are added 10 cc of hydrochloric acid and 15 cc of 2:1 nitric-perchloric acid mixture and 30 cc 0.3 Gm per cent lithium chloride solution. The sample is treated in the same manner as for plasma, except that the final volume is made up to 100 cc with distilled water.

#### APPARATUS AND PROCEDURE

The apparatus in use is an Applied Research Laboratories 15 meter grating spectriograph equipped with an ARL rotode, as shown in Fig 1. The rotode is driven by a synchronous motor supplied with a reduction system to control the speed of rotation. A high-purity carbon disk electrode  $\frac{1}{2}$  in in diameter and  $\frac{1}{8}$  in in width with a centered  $\frac{1}{8}$  in hole is attached to a carbon axle which is inserted in the rotating adapter of the electrode. This system forms the lower electrode of the spark stand (Fig 1, A). The upper electrode is a  $\frac{1}{4}$  in tapered high-purity graphite rod (Fig 1, B). A porcelain boat containing the prepared sample is arranged on an adjustable platform, which may be elevated to bring the solution into contact with the rotating disk (Fig 1, C). A speed of four revolutions per minute was found optimal for the analyses carried out in this study.

The excitation source used to vaporize the samples is an Applied Research Laboratories high-voltage spark source unit. The input is set at 240 volts. The rotary spark gap is adjusted so that the meter recording relative primary voltages reads 75 volts. Power is set at 2 kv-a. Full inductance of this unit is employed (setting at 8). The electrodes are pre-sparked forty seconds before the disk is brought into contact with the solution. A second pre-spark is carried out after immersion of the rotating disk to concentrate the solutes on the carbon

\*Perchloric acid should never be brought into contact with organic material in the absence of nitric acid because of the danger of explosion. The addition of nitric acid permits smooth oxidation of organic material with safety.

Fig 1—A Rotating disk electrode B Graphite rod electrode C Porcelain boat.

surface. Three separate exposures of forty seconds each are then made of a given sample. The light emitted by the vaporization of the solution is transmitted by means of a cylindrical lens through the slit of the spectrograph, dispersed by the grating and focused onto a 35 mm spectrum analysis #1 film. This film is developed using D 19 developer for two minutes at 70° F. A single film is sufficient for nine exposures.

Fig 2

This procedure obtains the quantitative spectriographic analysis of sodium, potassium, calcium, magnesium, and iron. The wave lengths found most suitable for quantitation are sodium, 3302.3 Å, potassium, 4044.1 Å, calcium, 3179.3 Å, magnesium, 2783 Å, iron, 3020.6 Å, lithium reference line, 3232.6 angstroms. The films are read on an ARL densitometer. Samples are generally run in lots of twelve. Approximately two hours are required from the beginning of sample preparation until results are available for the five metals in each of the twelve samples.

Synthetic standards, approximating the electrolyte composition of plasma and urine, are run at least twice daily as a control on spectriographic accuracy.

These standards are subjected to the same preparation as described for plasma and urine samples. Working curves and rapid calculating scales<sup>7</sup> are established from these standards so as to include a range covering one half to two times the expected concentrations (Fig 2)

TABLE I RESULTS OF SEVEN SEPARATE EXPOSURES OF A SINGLE SAMPLE OF PLASMA

to illustrate the percentage error of the spectrographic determinations. The error is usually within the range of plus or minus 5 per cent and almost always within plus or minus 10 per cent, regardless of the amount present in the samples. Determinations of Na, K, Ca, Mg, and Fe in the plasma of one hundred normal subjects are in progress and will be reported in a separate communication.

#### SUMMARY

A rapid and accurate method employing the emission spectrograph and featuring a rotating disk electrode has been described for the quantitative analysis of Na, K, Ca, Mg, and iron in plasma and urine.

## ANTITHROMBIN AND HEPARIN IN HUMAN BLOOD

T. A. LOONIS, M.D., PH.D.

SEATTLE, WASH.

HOWELL<sup>1, 2</sup> originally postulated the presence of a factor or its precursor in plasma which influences the antieclotting effect of heparin. The precursor he referred to as proantithrombin and the activated factor as antithrombin. It was believed that one of the functions of heparin is to promote the production of antithrombin from proantithrombin.

Heparin alone has little if any antithrombin activity when tested with purified fibrinogen and thrombin solutions. However, it is uniformly recognized that heparin appears to react with a substance present in normal plasma, leading to the formation of a substance which is capable of inactivating thrombin. Excellent reviews of the literature on heparin by Mason<sup>3</sup> and Eagle<sup>4</sup> discuss these factors. Quick reported that a normal antithrombic substance exists in the albumin fraction of plasma. He stated that heparin merely intensifies the existing antithrombic property of the albumin fraction. Astup and Darling<sup>5, 7</sup> have shown that slight amounts of an antithrombic substance exist normally in ox plasma and that this substance is not identical with the factor which is activated by heparin.

This report is concerned with the further identification of the factor in human plasma which in the presence of heparin results in the formation of an active antithrombic substance.

### EXPERIMENTAL PROCEDURE AND RESULTS

All early experiments were conducted on reconstituted dried normal human plasma (obtained from volunteers by the American Red Cross) or fractions obtained from this plasma by ammonium sulfate fractionation. Later experiments were conducted using human blood fractions obtained by the low salt low temperature alcohol fractionation method.<sup>8</sup> The experiments were conducted by mixing the various substances in serologic glass tubes which were supported in a constant temperature water bath maintained at a temperature of 38° C. In all experiments the various agents were added to the tubes in the bath in as rapid succession as possible from automatic pipettes, always adding the thrombin last. When the thrombin had been added the contents of the tubes were thoroughly mixed by vigorously swirling the tube in the air immediately above the bath. Clotting times were noted by an interval timer. The tubes were tipped every ten seconds or as often as necessary to determine the earliest formation of a definite gelatinous clot which could be observed grossly when the tube was tipped. Clotting times thus represent the time interval lapsing between the addition of thrombin and the formation of the clot.

An optimal concentration of heparin for use in the subsequent experiments was determined which would increase slightly the clotting time of plasma when added to a mixture of thrombin and plasma. The effect of varying the amount of thrombin was then determined. The results are shown in Fig. 1. The figure demonstrates that the ability of heparin

From the Department of Pharmacology, School of Medicine, University of Washington. This research was supported in part by a grant from the Abbott Laboratories, North Chicago, Ill.

Received for publication Dec. 1, 1948.

to prevent the clot formation is inversely related to the concentration of thrombin. The antithrombin activity resulting following the addition of heparin to plasma becomes markedly more evident as the thrombin concentration is diminished

Fig 1—The effect of heparin on the clotting time of reconstituted human plasma as produced by the addition of varying amounts of thrombin. Quantities of plasma as indicated are in milliliters thrombin (Thrombin Topical Parke-Davis) is in units and heparin (Lilly) is in milligrams. All volumes were made constant (10 ml) by the addition of citrate-phosphate buffer (MacIlvane's standard buffer solutions) of pH 7.3

Fig 2—The effect of heparin on the clotting time of partially purified human fibrinogen as produced by the addition of varying amounts of thrombin. Quantities of fibrinogen solution as indicated are in milliliters of 0.4 per cent solution of fibrinogen thrombin (Thrombin Topical Parke-Davis) is in units and heparin (Lilly) is in milligrams. All volumes were made constant (10 ml) by the addition of citrate-phosphate buffer of pH 7.3

The foregoing series of experiments was then repeated except that partially purified fibrinogen was substituted for the plasma. The fibrinogen was made in this laboratory by ammonium sulfate fractionation\*. The results are shown

\*This fibrinogen preparation was made by precipitation from reconstituted normal human plasma using 20 per cent saturation with ammonium sulfate. Removal of the precipitate by centrifugation and redissolving it in water and reprecipitating it two times with 20 per cent saturation of ammonium sulfate. The final precipitate was dialyzed using heavy-weight vegetable parchment casings in cold running tap water until the dialysate was free of sulfate. The dialyzed preparation was centrifuged and the precipitate was removed and dried in a desiccator divided into portions and stored at 0° C until used. When the preparation was used it was dissolved in 0.1N citrate phosphate buffer (MacIlvane's standard buffer solutions) of pH 7.3

in Fig 2 This figure shows that the rapidity of the conversion of the partially purified fibrinogen to fibrin in the presence of heparin and thrombin was inversely related to the amount of thrombin added Furthermore the clotting time of fibrinogen with thrombin in the absence of heparin was not influenced by the amount of added thrombin over the range studied The antithrombin activity which resulted following the addition of heparin in the presence of partially purified fibrinogen becomes more evident as the concentration of thrombin is diminished

Fig 3—The effect of heparin in the presence of plasmin (20-29% fraction) on the clotting time of partially purified human fibrinogen as produced by the addition of varying amounts of thrombin. Quantities of fibrinogen as indicated are in milliliters of 0.4 per cent solution of fibrinogen (Thrombin Topical Parke-Davis) is in units, heparin is in milligrams and the 20-29% ammonium sulfate fraction is in milliliters of 1.0 per cent solution of the fraction. Time is in minutes. All volumes were made constant (1.0 ml.) by the addition of citrate-phosphate buffer of pH 7.3

The next series of experiments involved the determination of the presence of a precursor of an antithrombin substance in the euglobulin fraction of normal human plasma. The euglobulin fraction (fraction obtained in the 20 to 29 per cent saturation range with ammonium sulfate) used in the experiments was made by the procedure outlined by Loomis, Charles, and Rider<sup>9</sup> which they used for the purification of fibrinolysin (plasmin)<sup>10</sup>. This fraction will be referred to in this paper as the plasmin fraction obtained by ammonium sulfate fractionation. Fig 3 illustrates the results when this fraction is added to the fibrinogen-thrombin-heparin mixtures. The figure illustrates that although the plasmin fraction has very little antithrombin property in itself, the clotting time is greatly prolonged in the presence of plasmin and heparin. In a similar type of experiment it was found that neither the 29 to 50 per cent nor the 50 to 75 per cent (albumin) fractions contained an antithrombin substance and they were not capable of being activated by heparin.

The next series of experiments involved the use of plasma fractions which were obtained by the low salt, low temperature alcohol fractionation technique. Fraction I was used as the source of fibrinogen. Fraction III-2 was used as the source of thrombin. Fraction III-3 (plasmin fraction) was tested for anti-

thrombin activity No antithrombin activity was found in this fraction Fraction III-3 was found to contain some traces of thrombin as evidenced by its ability, in high concentrations, to cause the clotting of fibrinogen

Fig 4 shows the results obtained using alcohol fractions The amounts of Fraction III-3 used in the experiments shown in Fig 4 did not contain a sufficient amount of thrombin to convert fibrinogen to fibrin The figure shows

Fig 4—The effect of heparin in the presence of Fraction III-3 (plasmin) on the clotting time of Fraction I (fibrinogen) as produced by the addition of varying amounts of Fraction III-2 (thrombin) Time is in minutes All quantities are in milligrams and all volumes were made constant (1.0 ml) by the addition of citrate-phosphate buffer of pH 7.3

that although neither heparin nor Fraction III-3 had a definite marked antithrombin action in themselves, when the two were added to a fibrinogen-thrombin mixture a definite marked increase in the clotting time resulted As the concentration of thrombin was decreased, the antithrombin action of the mixture of Fraction III-3 and heparin became more apparent

Further experiments demonstrated clearly that the precursor of the antithrombin was in Fraction III-3 and was inactivated after exposure to 70° for as short a time as one minute At 60° C the destruction of the antithrombin precursor was less rapid but occurred after five minutes of exposure It is stable at 40° for four hours In contrast to this, the exposure of heparin to temperatures as high as 90° C for five minutes did not influence its ability to activate the precursor of antithrombin in Fraction III-3

#### DISCUSSION

Howell<sup>1, 2</sup> believed that heparin prevented the clotting of blood by a dual action These actions are (1) stabilizing prothrombin through combination with it and (2) promoting the production of antithrombin from its precursor, proantithrombin Mellanby<sup>11</sup> believed that heparin does not act as an antiprothrombin but that its exclusive action is that of being capable of producing an

antithrombic substance in blood. Quick believed that heparin acts by activation of an antithrombin precursor which he stated was in the albumin fraction. The foregoing experiments did not show evidence of a normal antithrombin activity of the albumin fraction of reconstituted human blood. Furthermore, there was no evidence of significant amounts of antithrombin action of the plasmin fraction whether the fraction was made by ammonium sulfate or alcohol precipitation techniques. The fraction of human blood designated as the plasmin fraction (by ammonium sulfate fractionation) and Fraction III 3 obtained by the alcohol fractionation method showed muted antithrombin activity only in the presence of heparin.

In the experiments reported here when heparin is added to reconstituted normal human plasma or to partially purified fibrinogen in the presence of thrombin the clotting time was found to be inversely related to the concentration of thrombin. In such a test heparin appears to have a definite antithrombin activity. When heparin is added to Fraction I (fibrinogen) in the presence of Fraction III 2 (thrombin) obtained by low salt low temperature alcohol fractionation the clotting time is only slightly prolonged. In such a test no definite pronounced antithrombin activity for heparin could be demonstrated. This confirms previous work<sup>1, 2, 6</sup> which stated that heparin has no antithrombic action when tested on purified fibrinogen and thrombin.

The plasmin fraction obtained by ammonium sulfate fractionation and the plasmin fraction (Fraction III 3) obtained by alcohol fractionation were found to be practically free of inherent antithrombin activity. When heparin was added to either of these fractions in the presence of fibrinogen and thrombin the clotting time was greatly lengthened. The clotting time in such a test as that described is inversely related to the amount of added thrombin, therefore a true antithrombic substance is formed. In the presence of heparin the true antithrombin is formed from a precursor which is present in the plasmin fraction or Fraction III 3 and which has the characteristics of Howell's proantithrombin. It is inactivated rapidly by exposure to a temperature of 70° C.

#### SUMMARY

The effect of heparin on the fibrinogen-thrombin reaction in human blood is that of promoting the liberation of antithrombin from its precursor proantithrombin. Proantithrombin is present in the plasmin fraction obtained by ammonium sulfate fractionation and in the plasmin fraction (Fraction III 3) obtained by alcohol fractionation.

The author wishes to express his appreciation to Dr. F. F. Johnson of the Cutter Laboratories, Berkeley, Calif. for generously supplying the plasma samples obtained by alcohol fractionation methods. The technical assistance of Miss Evelyn Adams is gratefully appreciated.

## BONE MARROW STUDIES IN THE POLYCYTHEMIA OF HIGH ALTITUDES

CÉSAR F. MERINO, M.D., and CÉSAR REYNALVARJE, M.D.  
LIMA, PERU

IT IS generally accepted that the polycythemia found in men living at high altitudes results from the anoxia brought about by the low oxygen tension inspired air, acting on the erythropoietic organs which become hyperactive under such stimulation. Most investigators have observed in this polycythemia an increased percentage of reticulated red blood cells in the peripheral circulation, a finding which has been interpreted as evidence of hyperactivity in the formation of the erythrocytes. However, so far as can be determined no direct examination of the bone marrow tissues has been made in these permanent residents at high altitudes who have a reticulocytosis.<sup>1, 2, 3</sup> Thus, there is no direct evidence that reticulocytosis is paralleled by a corresponding hyperactivity in the blood forming organs. Such a study is presented in this paper. The results also contribute to an understanding of the etiologic mechanisms underlying polycythemias classified as secondary and as polycythemia vera. Bone marrow studies in the former group have been made occasionally<sup>4, 7</sup> but the findings are not definitive. The following two factors emphasize the importance of investigating this problem: (1) the increase in circulating total blood volume, an alteration which commonly has been considered as characteristic of polycythemia vera,<sup>8</sup> also may be present to a high degree in secondary polycythemias,<sup>3, 9, 10</sup> and (2) an increase in leucocytes and platelets in the peripheral blood, as well as splenomegaly, may be absent in some cases of polycythemia vera. These considerations indicate the desirability of investigating the possible value of the bone marrow examination as an additional diagnostic criterion in the study of the polycythemic conditions.

### MATERIAL AND METHODS

Sixteen men of Indian race, permanent residents in Cerro de Pasco, a mining center located in the Peruvian Andes region at an altitude of 4,390 meters (14,400 feet), were studied. According to previous investigations carried out in Peru,<sup>1, 11</sup> the arterial oxygen saturation of men living at this altitude averages about 83.0 per cent. All the men had been born in this area or in nearby localities also situated at high altitudes. Their age varied between 15 and 60 years. Six of the men had worked in the mines for some time. All of them were apparently in good health but no radiologic examination was carried out to eliminate the possibility of an existing pneumoconiosis in the group of miners. One native within this group presented an abnormal degree of cyanosis.

In each case a sample of venous blood was taken and bone marrow tissue was aspirated after a sternal puncture. The venous blood sample was used in the following determinations: the number of red blood cells, white blood cells and platelets per cubic millimeter, the hemoglobin in grams per 100 cc., and finally, the differential count of leucocytes. For this last

From the Department of Pathological Physiology and the Institute of Andean Biology, Faculty of Medicine.

Received for publication Dec. 20 1948

analysis films, Wright stained, were used. For the hemoglobin determination a Sahli hemoglobinometer, previously calibrated by means of comparative determinations made with this instrument and the Van Slyke manometric apparatus, was employed. Platelets were counted following the technique described by Dimeshek.<sup>12</sup>

The sternal puncture was performed at the level of the third intercostal space using a simple 16 gauge needle. About 0.5 cc of marrow material was aspirated,\* and fixed cover slip preparations were made promptly. The differential count of the bone marrow cells was made on the supravital preparations following the criteria established by Sabin and Miller<sup>13</sup> for cell identification. A total of 400 to 500 cellular elements was counted in each case.

#### RESULTS OBTAINED

*A. Peripheral Blood*—Data obtained from the peripheral blood are summarized in Table I. The number of red blood cells varied between 5.41 and 7.67 millions per cubic millimeter, with a mean value of  $6.45 \pm 0.29$  millions, the hemoglobin had a mean value of  $19.4 \pm 0.69$  Gm per 100 cc, with extreme variations of 16.5 to 25.6 grams. These findings are in agreement with those obtained by Hurtado, Merino, and Delgado<sup>3</sup> in the study of native residents at Morococha, at an altitude slightly more elevated than Cerro.

\*Neutral red and Janus green stains were used in the preparation of the supravital films following the techniques in use at Dr. Charles A. Doan's laboratory (Ohio State University, Columbus, Ohio). We feel that the supravital preparations afford a greater advantage than the fixed Wright stained films in the differential cellular study because the characteristics of the cells are better preserved. For a critical study of this problem see Epstein, R. D. and Tompkins, E. H. Comparison of Techniques for Differential Counting of Bone Marrow Cells (Guinea Pig) Am. J. M. Sc. 206: 249, 1943.

The number of leucocytes and platelets were within the normal limits of variation. Mean values observed were  $686 \pm 0.47$  and  $335.2 \pm 36.8$  thousands per cubic millimeter, respectively. The differential leucocytic count also was found to agree with normal established values.

Fig 1—Photomicrograph of bone marrow tissue obtained by sternal puncture showing an increase in cellularity (Case 1).

Fig 2—Photomicrograph of bone marrow (Case 1). Note predominance of erythroid cells.

### *B Bone Marrow —*

*I Macroscopic Examination* A crude attempt to evaluate the degree of hyperplasia was made by examining macroscopically the number and size of marrow particles in the aspirated material. It is realized that such an estimation lacks precision, but a rough comparison could be made with marrow samples similarly collected from many normal persons and patients with various types of blood dyscrasias at sea level. The degree of estimated hyperplasia was graded from 1 to 3 plus. From this estimation, it was felt that the marrow was hyperplastic in ten men (62.5 per cent) and normal in six (37.5 per cent).

*II Microscopic Examination* A similar attempt was made to estimate the relative cellularity of specimens by scanning the flecks of marrow on four different supravital preparations with magnifications of 100 and 450. The same observer examined all preparations. The basis for comparison was again the experience gained from similar examinations at sea level. Estimated hyperplasia was arbitrarily graded as from 1 to 3 plus. The marrow was thought to be hypercellular in thirteen of the subjects (81.2 per cent) and normally cellular in three. In all the supravital preparations, amorphous and fatty material could be identified within the nests of hematopoietic tissue, but in only one instance (Case 10) was the increase in these substances striking. The degrees of hyperplasia as estimated by these two methods were not always in agreement. Samples which were regarded as normal macroscopically were often considered hypercellular when observed microscopically. No exact correlation, furthermore, could be established between the degree of polycythemia in the peripheral blood and the estimated hyperplasia of the marrow. Figs 1 and 2 are photomicrographs which illustrate the increased cellularity of the marrow specimens.

A more detailed study of the cellular composition showed that there was regularly an erythroid hyperplasia of sufficient degree to make the nucleated red blood cells more numerous than granulocytes. This change coupled with the fact that the great majority of nucleated red cells were at the normoblastic maturation level\* caused the marrows to resemble those seen in the hemolytic anemias<sup>4, 5, 14, 15</sup> (Fig 3). In seven subjects (43.7 per cent) there was a moderate shift to younger cells of the erythroid series, early erythroblasts and megaloblasts were present in small numbers (Fig 4). Mitosis was frequently observed in the erythroid cells, but their number was not large.

The granulocytic elements were morphologically normal in all patients and showed no increase in younger forms of myelocytes. Polymorphonuclear leucocytes, metamyelocytes, and myelocytes "C" were the predominant elements in this series.

Megakaryocytes were seen in the thicker areas of the preparations. Most were mature in appearance, without qualitative changes and with multilobulated nuclei and a granular cytoplasm (Figs 1 and 2). None of the subjects showed the increase in megakaryocytes which so often is observed in polycythemia vera<sup>4, 5, 15-18</sup>.

\*The terminology of Sabin and Doan has been used throughout this paper for classifying the cells of both the erythroid and myeloid series.

Fig 3—Bone marrow tissue (Case 13) Shows numerous nucleated red blood cells in greater proportion to other cellular elements.

Fig 4—Bone marrow tissue (Case 1) Illustrates relative increase of young erythroblasts (marked with arrows)

Small lymphocytes were found in small numbers ( $0.6 \pm 0.14$  per cent) in nearly all of the samples examined but were less frequent than is usually accepted as normal<sup>5 15 17</sup> Clasmatoocytes with or without signs of phagocytosis, were observed in all cases but in only two instances (Cases 8 and 10),

N Normal (as it is found in healthy people at sea level)

in which these cells averaged 5.1 and 4.2 per cent, was then number sufficiently large to be significant. Mature plasma cells, monocytes, and reticular cells were seen occasionally.

*III Differential Count of the Bone Marrow Cells* In all instances, the percentage of each type of cell (myelogram) was determined in the supravital preparations. From 400 to 500 cells were identified in each count. Table II gives the results obtained in this study. It is realized that the significance of a quantitative study of bone marrow cells in samples obtained from a single sternal aspiration is limited.<sup>15 19 20 21</sup> However, if the interpretation is related to the general impression derived from a careful study of several preparations, such quantitative evaluation acquires a greater value. The predominant cells in the myeloid series were found to be myelocytes "C" ( $13.8 \pm 0.56$  per cent), metamyelocytes ( $9.3 \pm 0.46$  per cent), and segmented neutrophils ( $9.1 \pm 0.94$  per cent) (Table II). Comparison of these figures with those given for healthy men living at sea level indicates that the mean percentage of myelocytes found in our subjects agrees very closely with those given by Scott<sup>5</sup> and by Wintrobe.<sup>15</sup> 13.1 and 12.0 per cent, respectively. On the other hand, our mean percentage values for metamyelocytes and segmented neutrophils, 9.3 and 9.1 per cent, respectively, were lower than those found

by the same investigators at sea level 15.7 and 14.8 per cent (Scott) and 20.0 and 22.0 per cent (Wintrobe). This relative decrease in the percentage of mature cells of the myeloid series cannot be interpreted as an indication of a shift to younger forms because the younger elements of this series myelocytes "A" and "B" and myeloblasts did not show a corresponding increase.

The most common cell in the erythrocytic series was the normoblast 41.9 ± 1.05 per cent with variations between 35.4 and 49.7 per cent. This means percentage value found in the high altitude residents is definitely higher than that obtained by Scott and by Wintrobe<sup>15</sup> in the bone marrow of healthy adult subjects living at sea level 17.8 and 18.0 per cent respectively.

The level of polycythemia observed in the peripheral blood did not show a constant relationship to the degree of erythropoietic hyperplasia in the bone marrow or to the changes found in the proportion of the different erythrocytic cells in this organ. Calculation of the quantitative relationship between the erythroid and myeloid cellular elements (M/E ratio) gave the following mean percentage values:

Granulocytic series (myeloid)	40.9 per cent
Erythrocytic series	55.6 per cent
Other cellular elements	3.5 per cent
M/E ratio	1 to 1.4

	SEA LEVEL	HIGH ALTITUDE
MYELOID CELLS	75 0 %	40 9 %
ERYTHROID CELLS	20 0 "	55 6 "
OTHER CELLS	5 0 "	3 5 "

Fig 5—Graphic representation of the M/E ratio in bone marrow differential count made in residents at sea level and at high altitudes

These figures demonstrate that there is a very definite relative increase at high altitudes in the erythrocytic cells in the bone marrow, as compared with sea level (Figs 2 and 3). Our M/E ratio of 1 to 1.4 differs considerably from those of 3 to 1 or 4 to 1 considered as normal at sea level. A graphic representation of this observed ratio is given in Fig 5.

#### DISCUSSION

The observations just described indicate that there is an erythroid hyperplasia of the bone marrow in healthy people living permanently at high altitudes. The consistency of the results makes them seem valid even though the hazards of estimating hyperplasia from a single aspirated sample of marrow are recognized and admitted. The mean percentage value of 55.6 obtained for the erythrocytic elements, as compared with 40.9 per cent for the myeloid cells, in our subjects, is definitely higher than the corresponding values found at sea level by a number of different investigators. Doan,<sup>22</sup> 4 to 13 per cent, Manning,<sup>23</sup> 16.7 per cent, Mendell and others,<sup>24</sup> 15.4 per cent, Osgood and Seaman,<sup>25</sup> 17.2 per cent, Wintrobe,<sup>15</sup> 22.0 per cent, Piney and Hamilton,<sup>26</sup> 18 to 25 per cent, Young and Osgood,<sup>27</sup> 14.1 per cent, and Scott,<sup>5</sup> 17.8 per cent. Furthermore, as already has been indicated, our mean value of 1.0 to 1.4 for the M/E ratio in the high altitude subjects differs greatly from the ratios of 3 to 1 and 4 to 1 accepted as normal in healthy adults living at sea level.<sup>15, 25, 27</sup>

Quantitative study of the erythrocytic cells in the bone marrow showed a normal maturation process, with the normoblast being the predominant cell, while the more primitive ones, the erythroblasts and the megaloblasts, were found to be normal or only slightly increased. In consequence, the hyperplasia of the bone marrow in the high altitude subjects can be classified as normoblastic in nature or occasionally as normo erythroblastic.

It is interesting to compare our findings with those described in the studies made of the bone marrow in other cases of polycythemia, especially polycythemia vera. The bone marrow in this latter disease has been described as hyperplastic by some investigators<sup>4 15 17 28</sup> while others such as Markoff, Nordenson, Rohi, Mallarme and Klum (quoted by Scott<sup>5</sup>) and Manning<sup>23</sup> concluded that increased cellularity is not a characteristic finding. In some of the cases of polycythemia vera which showed hyperplasia the process affected all cell elements of the bone marrow (panhyperplasia)<sup>4 15 28</sup>, the M/E ratio, therefore, was found to be normal or very little changed. In these instances the generalized hyperplasia appears different from the partial hyperplasia only erythrocytic in nature found in our cases of the polycythemia of high altitudes.

Other patients with polycythemia vera have been described as showing a definite hyperplasia of the erythrocytic cells of the bone marrow<sup>5 3 4</sup>, in these instances the proportion of nucleated red cells varied between 30 and 45 per cent of the number of cells counted and there was no evidence of a maturation arrest. These changes although similar in some respects to those observed by us in the polycythemia of high altitudes differ in other fundamental aspects. Most investigators agree that the bone marrow myeloid cells in cases of polycythemia vera show not only an increase in number but also an increase in younger forms such as young myelocytes and myeloblasts<sup>5 15 17</sup>. Furthermore, a remarkable increase in the number of megakaryocytes in the bone marrow of patients with polycythemia vera has been described as a frequent finding<sup>4 6 1 18 20</sup>. Those changes were absent in the subjects studied by us at high altitudes.

The results obtained in the present investigation agree closely with the observations made by Hurtado Meimo and Delgado<sup>3</sup> on the peripheral blood of a large number of permanent residents at high altitudes. These workers found no evidence of hyperactivity in the production of leucocytes. They indicated that anoxia appeared to be a specific stimulant for erythropoietic activity, leaving unaffected the formation of white blood cells. Our studies of the bone marrow cytology at high altitudes confirm that opinion and in addition emphasize the difficulties in accepting that concept that anoxia plays a fundamental etiologic role in the development of polycythemia vera.<sup>29</sup>

Schleicher<sup>30</sup> and Sundberg<sup>17</sup> have described volumetric variations in the different layers of the bone marrow and the latter investigator is of the opinion that the fat layer is nearly always absent in cases of polycythemia vera.<sup>31</sup> The supravital preparations in our cases always showed fat globules, but this observation cannot be used for comparison with the results in polycythemia vera.

Unfortunately, very few studies have been made on the cellular characteristics of the bone marrow in cases in which polycythemia has developed as a consequence of an anoxic condition brought about by respiratory or circulatory alterations. Zuntz, Loewy, Muller, and Caspary<sup>7</sup> and Dameshek<sup>4</sup> have reported cases of secondary polycythemia in which the bone marrow changes have been similar to those observed in polycythemia vera. On the other hand, Kienle<sup>6</sup> obtained results comparable to ours. It is desirable to have a greater number of observations in these cases in order to reach a better understanding of the value of sternal puncture in the differential diagnosis of the various types of polycythemia. Our study seems to indicate that at least the polycythemia of high altitudes, which is of secondary type, developing as a result of a known anoxic stimulus, differs in the cytologic characteristics of the bone marrow from most cases of polycythemia vera, a disease in which the etiologic mechanism is unknown.

#### SUMMARY AND CONCLUSIONS

The bone marrow of sixteen, healthy, Indian natives of adult age, permanent residents in Cerro de Pasco at an altitude of 4,390 meters (14,400 feet), was studied. Samples were obtained by means of sternal aspiration, and supravital and Wright stained preparations were used for the qualitative as well as quantitative microscopic examinations. All men showed a definite polycythemia in the peripheral blood.

The results obtained were compared with previous observations made in healthy people living at sea level and in patients with polycythemia vera.

1 The bone marrow of healthy, adult natives, living permanently at an altitude of 4,390 meters (14,400 feet), was interpreted as showing hyperplasia (hypercellularity) in 81.2 per cent of the subjects examined.

2 This hyperplasia was characterized by a marked increase of the cells of the erythroid series over the myeloid cells. Normoblasts were the most predominant cellular elements (normoblastic hyperplasia), and a reversed M/E ratio was a constant finding. The degree of hyperplasia was not always proportional to the level of polycythemia found in the peripheral blood.

3 Myeloid cells and megakaryocytes were not increased and the maturation process was normal in both the erythroid and myeloid series.

4 The foregoing findings seem to confirm further the opinion, previously expressed and derived from studies on peripheral blood, that anoxia acts as a specific stimulus for an increased activity in the formation of the erythroid cells leaving the myeloid cells unaffected.

5 A comparative study of our findings and those obtained in similar investigations made by several observers in cases of polycythemia vera seems to indicate that in general, the bone marrow cytology and the degree and kind of hemopoietic hyperactivity are not similar in the polycythemia of high altitudes and in polycythemia vera. This fact does not conform with the theory that anoxia is the underlying etiologic factor in the latter disease.

## PLASMA TOCOPHEROL LEVELS IN VARIOUS PATHOLOGIC CONDITIONS

HANS POPPFR, M D , P H D , ALVIN DUBIN, M S , FREDERICK STEIGMANN, M S ,  
M D , AND FRANK P HESSER, B S  
CHICAGO, ILL

THE blood concentration of vitamins depends not only on exogenous factors such as nutrition but also to a great degree upon endogenous processes such as diseases. Some evidence has been presented that the plasma level of the tocopherols reflects the nutritional status in that it is reduced in malnutrition<sup>1</sup> and sprue<sup>2</sup> but not in fibrositis<sup>3</sup>. The effect of disease upon the plasma tocopherol is not established. The influence of various diseases and especially those of the liver upon the metabolism and plasma level of vitamin A has been the subject of intensive investigations<sup>4-5</sup>. It has been shown that in the acute stage of hepatic disease the plasma vitamin A is lowered, less as the result of faulty intestinal absorption than of deficient release of vitamin A from the liver. This theory is based upon fluorescence microscopic findings which in hepatic damage revealed displacement of vitamin A from its original sites within the liver cell to abnormal locations<sup>6</sup> and upon chemical analyses which suggested a defect in hepatic vitamin A esterase<sup>7</sup>. The plasma vitamin A level can thus, under certain circumstances, become an index of hepatic function. The question arose as to whether the metabolism of vitamin E as another fat soluble vitamin A is subject to similar influences by the liver. This question is of significance since vitamin E has a protecting influence upon the liver in carbon tetrachloride intoxication<sup>8</sup> and in experimental nutritional injury<sup>9-10</sup>. Moreover, the recently claimed beneficial effect of vitamin E in vascular diseases<sup>11</sup> makes such a study desirable.

The plasma tocopherol level in various normal and abnormal conditions, both before and after the intake of a test dose of tocopherol, was determined. It was compared with the plasma vitamin A alcohol and ester. In addition, the concentration of tocopherol in human liver and bile under normal and pathologic conditions was determined. This study was facilitated by the recent development of methods for the chemical determination of tocopherols in organs and plasma<sup>12-14</sup>.

### MATERIAL AND METHODS

Tocopherol in serum and bile was determined by the method of Quarfe<sup>12,13</sup> and in the liver by the methods of Hines<sup>14</sup> with Quarfe's modifications for colorimetric assay. The plasma vitamin A was determined by the method of Kimble<sup>15</sup>, the partition, according to the recently used modification of Gillam<sup>16</sup>. Plasma tocopherol was determined before breakfast on nine normal subjects (technicians, interns, nurses) and seventy one patients suffering from various diseases. In ten instances, the determination was repeated three,

Received for publication Jan. 26, 1949.

six (or seven), and twenty four hours after the intake of 1,500 mg of mixed tocopherol.\* The time interval was chosen from experiences with the response of the plasma vitamin A level to the intake of large doses of the vitamin.<sup>17</sup> The bile was obtained from patients in whom, during operation, biliary drainage was established. It was collected after biliary secretion appeared normal as to amount and appearance. The liver specimens were obtained at autopsy.

## RESULTS

As Table I shows, the results in normal subjects agreed well with the reports in the literature. In miscellaneous diseases the range was significantly widened. In nephritis the level as a rule was much higher than in normals, in nephrosis, less so. In heart diseases the level was consistently higher than in normals and the highest level found occurred in this group. In liver diseases without biliary obstruction as in infectious hepatitis or cirrhosis without jaundice, the level was slightly but not significantly lower than in the normals. In obstructive jaundice, it was though not regularly higher than in normals. In one case of xanthomatous biliary cirrhosis it was only slightly elevated. In patients with toxic hepatitis and cirrhosis with jaundice it was slightly higher than in normals but in some it was low. In carcinoma other than that of the biliary tract there was a tendency for the level to be slightly higher than normal. One case of malnutrition showed normal values.

TABLE I. TOCOPHEROL CONCENTRATION IN THE PLASMA OF NORMAL SUBJECTS AND OF PATIENTS SUFFERING FROM VARIOUS DISEASES

DIAGNOSIS	NUMBER OF CASES	TOCOPHEROL CONCENTRATION IN MG/100 CC PLASMA		
		AVERAGE	MAXIMUM	MINIMUM
Normals	9	0.94	1.38	0.51
Miscellaneous diseases	7	1.13	2.40	0.15
Nephritis	5	1.55	1.92	1.02
Nephrosis	4	1.16	1.68	0.81
Heart diseases	9	1.78	2.52	1.20
Infectious hepatitis	9	0.87	1.86	0.45
Toxic hepatitis	5	1.36	1.83	1.17
Cirrhosis without jaundice	6	0.92	1.94	0.39
Cirrhosis with jaundice	14	1.26	2.28	0.51
Obstructive jaundice	7	1.61	2.51	0.36
Carcinoma other than in biliary tract	5	1.43	1.62	0.78

A plot of the tocopherol level with the plasma vitamin A level failed to reveal a significant correlation (Fig 1). There was also no correlation between plasma level of tocopherol and that of vitamin A alcohol or ester.

TABLE II. TOCOPHEROL CONCENTRATION IN PLASMA AND BILE

DIAGNOSIS	TOCOPHEROL IN MG/100 CC	
	BILE	PLASMA
Stricture of hepatic duct	0.66	
Choledocholithiasis	2.60	
Choledocholithiasis	0.76	0.90
Choledocholithiasis	1.40	1.17
Choledocholithiasis	0.74	1.29

\*Kindly supplied by Hoffmann-La Roche Inc. Nutley N. J. as Ephynal Acetate (d 1 alpha tocopherol acetate) tablets of 50 milligrams.

Fig 1—Plot of the plasma tocopherol level against the plasma level of total vitamin A

Fig 2—Response of the plasma tocopherol level to the intake of 1500 mg mixed tocopherol in oil in normals and in patients suffering from various diseases

The bile obtained from patients with operative bile fistulas revealed tocoopherol concentrations of about the same range as the plasma (Table II). In the three instances in which both were determined at the same time on the same patient, there was a moderate parallelism.

After intake of a large test dose the plasma tocopherol level rose significantly and regularly in normals, whereas in patients with acute hepatitis or cirrhosis the rise was, though not regularly, depressed or absent. In one case of obstructive jaundice the level rose significantly from a high fasting level. In one patient with nephrosis, the rise was insignificant (Fig. 2).

In two patients with liver diseases the tocopherol concentration of the liver was significantly lower (Laennec's cirrhosis 0.441 mg per 100 Gm obstructive jaundice, 0.944 mg per 100 Gm) than in two others dying from diseases not related to the liver (carcinoma of colon 2.639 mg per 100 Gm, cor pulmonale 3.374 mg per 100 Gm).

#### DISCUSSION

The variations of the plasma tocopherol level in pathologic conditions reveal no correlation with those of the plasma vitamin A level. The significant and characteristic decrease of the plasma vitamin A level in liver diseases and other severe conditions does not hold true for the tocopherol level. The latter reveals a slight tendency to be lower in pure hepatocellular disease but a definite tendency to be higher in obstruction of the biliary tract. This is also reflected in the elevated levels in cirrhosis with jaundice. This behavior parallels that of cholesterol which is also elevated in some hepatobiliary diseases, supposedly because of impaired biliary excretion. However, the concentration of tocopherol in the bile does not exceed its plasma concentration in contrast to cholesterol. Other factors therefore, have to be considered for the elevation of the plasma tocopherol level in obstructive jaundice. Its slight reduction in hepatocellular damage could be in keeping with the significantly lowered tocopherol concentration in the liver, in nonhepatic diseases the range of the hepatic tocopherol concentration agrees with that reported in animals.<sup>1</sup> Whether poor intestinal absorption of tocopherol in oil—already previously demonstrated in cirrhosis<sup>1</sup>—is the only factor explaining the low hepatic stores in liver diseases remains to be established.

The plasma tocopherol level is elevated in a variety of diseases e.g. carcinoma, even if not involving the biliary tract. The elevation in nephritis in contrast to nephrosis parallels the behavior of vitamin A but not of cholesterol.<sup>1</sup> The rather constant elevation in cardiac diseases does not speak for a vitamin E deficiency in such conditions. The latter has been assumed as rational for the treatment of heart diseases with high doses of vitamin E. The elevation of the plasma tocopherol in pathologic conditions requires further study which should be associated with the clarification of the biochemical function of vitamin E as an antioxidant.

#### SUMMARY

1 The variations of the plasma level of tocopherol in various diseases do not parallel those of vitamin A and therefore the metabolism of vitamin E is influenced by endogenous factors in a different fashion from that of vitamin A.

2 Plasma tocopherol is only slightly and not consistently reduced in hepatocellular damage. It is increased in obstructive jaundice, carcinoma, nephritis (but not nephrosis), and most consistently in cardiac diseases.

3 The tocopherol concentration of the bile shows a moderate parallelism to that of the plasma.

4 The normal rise of the plasma tocopherol following the intake of large doses of tocopherol in oil is often absent in liver diseases.

5 In the few instances studied, the hepatic tocopherol concentration was lower in patients with liver diseases than in those dying from other diseases.

6 The reduction of the plasma tocopherol in liver diseases may be related to the factors mentioned. Its elevation in various other diseases is thus far not explained.

## EVALUATION OF THE FLOCCULATION TEST WITH HAYEM'S SOLUTION

EMANUEL E. MANDEL, M.D.,\* AND DELMO A. PARIS, M.D.,†  
CHICAGO, ILL.

WITH THE TECHNICAL ASSISTANCE OF DIANE T. HARRIS, B.S.‡

**D**IAGNOSTIC problems as they arise in the care of jaundiced patients often call for more or less elaborate examinations which are not readily available to the average physician.<sup>1,3</sup> Hence, a simple serum reaction with Hayem's solution, reported to be a useful aid in the management of hepatic disorders,<sup>2,4,10</sup> appeared to be worthy of study. With an appraisal of its practical value as the chief aim, the test was applied to a general hospital population and its results correlated with pertinent clinical and laboratory findings.

### MATERIAL AND METHODS

In initial experiments titration of fresh serum with Hayem's solution by daylight as prescribed in Gros' method<sup>4,7</sup> was found to yield inconsistent results. The two end points "reversible" and "irreversible" flocculation, differed in the same specimen with different observers, with varying intensities of illumination, and with changes in the rate of titration. Because of these and other shortcomings, the method was modified and standardized, as follows. Equal volumes of serum and the reagent (usually 1 ml. of each) are mixed, a procedure first employed by Jacobson<sup>17</sup>, development of a precipitate ("irreversible flocculation") within one to twenty-four hours is considered a positive reaction which may be graded as one, two, and three plus according to the amount of precipitate. An immediate prediction of the eventual outcome of the test can usually be made by first overlaying the serum with 1 drop of Hayem's solution while a faint transient clouding is seen with proper artificial light in any (normal) serum a well discernible "reversible flocculation" is an abnormal finding ("Gros reaction"). The results of this combined Gros-Jacobson or Hayem's (H) test, as designated hereafter are consistent and uninfluenced by accidental hemolysis or prolonged refrigeration of the serum but may be interfered with by heavy lipemia. The Hayem's solution used in this study contains 1.0 per cent sodium chloride according to the Swiss Pharmacopoeia and as described by Gros.<sup>6</sup> The solution generally employed in this country containing 0.5 per cent sodium chloride was found by us to produce precipitates in the sera of obviously healthy persons and consequently to be of no diagnostic value. There is no difference however in the value of either reagent in the performance of red blood cell counts.

The H test was performed on sera from 550 clinic and hospital patients. As a rule, either serum left over after the routine performance of the Kahn test or part of a fasting blood sample drawn for other diagnostic procedures was used. These included in 300 patients, one or more of the tests listed in Table I. The modification of the Takata-Ara procedure employed<sup>20</sup> was chosen because it allows grading of the reaction more readily than the original technique.<sup>21</sup> Weak reactions (flocculation beyond the second test tube) were included among the positive results. "Gamma globulin" as referred to in the tables and text, signifies the results of the precipitation method using ammonium sulfate.<sup>9</sup> This method

yields an average of 85 per cent of the true gamma fraction. The borderline between abnormal and normal results of all the comparative tests was drawn so as to include only definitely pathologic reactions in the first group, mostly in accordance with recommendations by other authors (Table I).

#### RESULTS AND COMMENT

The significant clinical and laboratory findings in 300 patients are listed in Table II. Two hundred fifty volunteers, employment examinees, and patients admitted for orthopedic conditions or for elective surgery served as a control group in which the H reaction was consistently found to be negative.

Hyperglobulinemia and high gamma globulin fractions were prevalent in the group of H-positive sera (Table II, A). This fact and a similar parallelism in results with the other studies listed seem to illustrate the mechanism of the H test. The chemically related Takata procedure showed the best agreement though lower sensitivity—in accordance with observations made by other authors comparing the Takata with the G<sub>10</sub>s test.<sup>5 6 10, 11 14, 15</sup> Formation of a precipitate in a mixture of serum with a solution of mercury bichloride evidently depends on the presence of high-molecular protein fractions.<sup>5 6 10 21 26 30, 32</sup>

Gamma and total globulin levels, known to be major factors in all the reactions studied and especially in the zinc sulfate test,<sup>15 19, 21 26 30 43</sup> were found to be moderately raised in some H-negative sera (Table II, B). Apparently, the increase must be considerable in order to produce an H flocculation, in contrast to the highly sensitive zinc sulfate turbidity. Hence, a mild hepatitis or an early stage of the disease may not be expected to influence the H test.<sup>21 31 32 39, 44 48</sup> A return to normal of a formerly positive reaction may herald recovery. This, indeed, was our experience in many instances of primary hepatic and other disorders, such as thyrotoxicosis and acute and chronic infectious processes.

There are many disorders "not primarily hepatic"<sup>49</sup> in which the plasma gamma globulin is commonly found to be augmented.<sup>32 33 37 46 47 50 51</sup> They include all those in which a positive H test was encountered, save for thyrotoxicosis.<sup>32, 46, 47, 55</sup> In all of them the occurrence of positive sedimentation and flocculation tests has been reported.<sup>3 27 30 32 36 38 39 42 43 47 49 56 60</sup> and is again demonstrated in this study. Used singly as a screening method, any one of them,

including the H test, would essentially be a potential indicator of one thing only organic disease, one of the many causing physicochemical plasma alterations. The lines drawn by the various procedures, and the size and character of the diagnostic groups encircled by them, differ according to the finer mechanism of each test in which qualitative changes of the gamma fraction other globulins alterations in the albumin and lipid contents may play a role.

In our material, the Takata and Hanger tests would appear to be the least sensitive ones, separating only 12.1 and 13.5 per cent respectively, of 300 cases as "disease suspects." Next in relative sensitivity was the formol gel test picking up 16.5 per cent then the thymol turbidity and Hayem tests (both about 26 per cent) the sedimentation rate (51.5 per cent), and, finally, the zinc sulfate turbidity test (62.6 per cent). There was variation not only in number but also in type of cases among those "groups of suspects," as exemplified by the incidence of primary hepatic disease in each. Of the group defined by a positive Takata reaction, about 30 per cent had either hepatitis or cirrhosis of the group with a positive cephalin cholesterol flocculation, 48 per cent, of the positive formol gel group, 21 per cent, of the positive Hayem's, 22 per cent, of the positive thymol turbidity 49 per cent, of the elevated sedimentation rate, 10 per cent and of the group with a positive zinc sulfate turbidity 18 per cent. Taking all the cases of primary hepatic disease encountered, the percentage of positive reactions was 20 with the use of the formol gel test, 35 with the Takata A11 method 58 with the cephalin cholesterol flocculation, 63 with the H test 75 with the sedimentation rate 78 with the thymol, and 89 with the zinc sulfate turbidity test. Hence, in grading these procedures as to their relative value in detecting hepatic disorders, the formol gel and Takata tests would be on the bottom and the two turbidity reactions on top of the scale. Since all these tests except the cephalin cholesterol flocculation, yielded positive results in the later stages of obstructive jaundice (Table II A) they cannot be relied upon, singly for differentiation between "medical" and "surgical" jaundice. While, in this regard, the cephalin cholesterol flocculation exhibited the greatest diagnostic selectivity, the H test appeared to possess prognostic value since it pointed out the most severe forms of hepatitis and all cases of cirrhosis, as well as the more prolonged and complicated instances of biliary obstruction.

A positive H flocculation occurred in all cases of active rheumatoid arthritis, in 10 per cent of the cardiac group, in 51 per cent of acute infectious diseases in 47 per cent of chronic lung disorders and in 59 per cent of malignant neoplasms. It implied systemic illness usually denoting the more serious and/or advanced case and was more ominous than the abnormal outcome of the routine sedimentation test at times even coinciding with a normal rate. There were no false positive reactions. In some instances a positive H test was the first abnormal sign demonstrable followed sooner or later by the detection of a major illness such as cirrhosis syphilis pyonephrosis pleuritis

active tuberculosis, metastatic neoplasm. The test was helpful in such differential diagnostic questions as early obstructive or hepatic jaundice, tumor of the right kidney or hepatomegaly, epistaxis due to nasal lesion or to chronic hepatic disease, cholecystopathy or neoplastic liver involvement, "rheumatism" or rheumatoid arthritis, congestive or infectious pleural effusion, nutritional or leucemic anemia. A positive reaction favored, a negative one was against, the hepatic, infectious, or neoplastic disorder under consideration. While in such problems the quantitative analysis of the blood proteins would represent a more accurate index,<sup>2, 3, 25, 29, 32, 37, 46, 47, 50, 55</sup> the quick orientation afforded by the test proved to be valuable and seldom misleading.

A correlation of all positive H reactions with a significant increase in gamma globulin could either be demonstrated or, clinically, postulated, except for the two cases of hyperthyroidism. The results found in this condition point to a rise in serum alpha globulin and/or a fall in albumin<sup>32, 46, 47, 55</sup> as possible additional factors in the mechanism of the H test. A negative H reaction does not seem to rule out any of the ailments summarized, with the exception, perhaps, of cirrhosis of the liver and active rheumatoid arthritis—if such conclusions are permitted on the basis of the small number of such cases studied.

It appears reasonable to include the H test in the category of serologic "liver function" tests. While all these reactions reflect serum protein changes which are common diagnostic features of liver disease, they are to be attributed largely to the general phenomenon of reticuloendothelial irritation quite independent of liver function.<sup>1, 3, 23, 31, 32, 36, 39, 57</sup> Since the morbid processes in this group, including those enumerated, constitute a major part of everyday practice, the chief value of the H test seems to lie in its nonspecific screening capacity, calling attention to the presence of organic disease, much like the sedimentation rate but quite different in scope. When used as a quick office procedure, it is apt to point out the more severe forms of those conditions, it may further provide ready supplementary evidence and serve as a prognostic guide. While in the diagnosis of liver disease it appears qualitatively inferior to some of the standard tests in use, the clean-cut objective results of the H reaction and the simplicity in technique, requiring no instrument, constitute practical advantages. These facts, and the general availability of the reagent should favor the adoption of the test as a routine clinical procedure.

#### SUMMARY

Results of a serum flocculation test with Hayem's solution (H test) were compared with those of standard flocculation reactions, erythrocyte sedimentation rate, and serum protein fractionation.

Of 550 persons screened with the test, all of the 78 (14 per cent) who showed a positive flocculation had a systemic illness of either metabolic, infectious, or neoplastic nature. Similar diseases occurring in some of the H-negative cases were usually milder or less advanced. Serum globulin alterations,

as reflected by the comparative procedures, appeared to be the major factors producing a positive reaction.

In the diagnosis of liver disease, the II test was found to be less specific than some of the other flocculation tests but was superior to most of them by consistently yielding a positive result in all instances of hepatic cirrhosis. A similar observation was made in active rheumatoid and infectious arthritis.

The test is recommended as a simple office procedure which can provide diagnostic information comparable to that obtained with more elaborate flocculation reactions.

## THE COLLOIDAL RED TEST AS AN INDEX OF LIVER DYSFUNCTION

ELLIOT OPPENHEIM, M D , MAURICE BRUGER, M D , AND ELSIE FROST, B A  
NEW YORK, N Y

THE colloidal gold test as modified by Maclagan<sup>1</sup> is recognized as a valuable test in the study of liver dysfunction. However, the preparation of the gold sol is time consuming and tedious, these facts have restricted the wider clinical application of the test. In 1947, Ducci<sup>2</sup> recommended a procedure in which a modified scarlet red solution is used and which is carried out following the general principles of Maclagan's colloidal gold reaction. The preparation of this solution is simple and the suspension is more stable than the gold sol. In the present clinical study, the colloidal red test was compared with two other recognized methods of a similar category, namely, cephalin-cholesterol flocculation and thymol turbidity, in 122 subjects. These included twenty normal individuals, eleven patients with infectious hepatitis, seven with portal cirrhosis, eleven with chronic cholangitis, twenty-two with chronic cholecystitis and cholelithiasis, seven with malignancy of the gastrointestinal tract and liver metastases, and forty-four patients with miscellaneous disorders.

### METHODS

The cephalin-cholesterol flocculation test was carried out as introduced by Hanger<sup>3</sup> and modified by Neefe and Rheinhold.<sup>4</sup> Values exceeding 2+ flocculation were interpreted as abnormal. The thymol turbidity test was performed by the method of Maclagan.<sup>1</sup> The procedure was modified by adding 0.1 cc of serum to 6 cc thymol buffer solution. Values exceeding 4 units were considered abnormal. The colloidal red test was carried out according to the procedure outlined by Ducci.<sup>2</sup> Values exceeding 2+ flocculation were considered abnormal.

### RESULTS

Table I shows the results obtained in twenty normal individuals free of liver or biliary tract disease. It will be noted that in no instance was the colloidal red flocculation greater than 2 and this occurred in only two of the twenty subjects.

Table II details the results in eleven cases of infectious hepatitis (epidemic and homologous serum varieties). It will be noted that the colloidal red agreed with the cephalin-cholesterol flocculation in nine instances. In one of the remaining two cases (Patient 1), the cephalin-cholesterol and thymol turbidity tests were negative while the colloidal red was 3+. In the other (Patient 5), cephalin-cholesterol flocculation was 3+ while the other tests were normal. Thymol turbidity compared favorably with the colloidal red test in eight of the eleven patients. In the other three, the thymol turbidity reaction was within normal limits while the colloidal red precipitation was definitely abnormal.

From the Department of Medicine, Post-Graduate Medical School, New York University-Bellevue Medical Center.

Received for publication Feb. 7, 1949.

Table III shows the results in seven cases of portal cirrhosis. The cephalin cholesterol flocculation and colloidal red tests agreed in five instances. In the remaining two cephalin cholesterol flocculation was normal while colloidal red precipitation was abnormal. Thymol turbidity and colloidal red precipitation compared favorably in five of six cases. In the remaining instance thymol turbidity was normal whereas the colloidal red precipitation was abnormal.

Table IV details the results in twenty-two cases of chronic cholecystitis with stones. Two subjects (Patients 14 and 17) had associated common duct stones verified at operation. In none of these was a positive colloidal red test obtained. In one instance (Patient 17), the cephalin-cholesterol test was 3+, thymol turbidity 5 units, and the colloidal red flocculation at the upper limit of normal.

Table V indicates the results in eleven cases of chronic cholangitis. In six patients the cholangitis was due to bacterial infection (*Escherichia coli*). In eight, there was good agreement between the cephalin-cholesterol flocculation and the colloidal red tests. In the other three, cephalin-cholesterol flocculation was normal while the thymol turbidity and colloidal red tests were abnormal.

The thymol turbidity and colloidal red reactions agreed in ten of the eleven cases. In the remaining one both the cephalin cholesterol and thymol turbidity tests were abnormal whereas the colloidal red precipitation remained normal.

Table VI shows the results in seven cases of malignancy of the gastrointestinal tract with secondary metastases to the liver. In only one patient was an abnormal flocculation test observed. A 3+ colloidal red reaction. Apparently the colloidal red test is of no greater value in detecting carcinomatosis of the liver than the other flocculation tests.

Table VII details the findings obtained in forty-four patients with various diseases. It will be noted that in ten instances an abnormal colloidal red test was obtained. These included two patients with scleroderma, two with diabetes mellitus, one with chronic rheumatoid arthritis, one with chronic arthritis due to gout, one with thyrotoxic heart disease, one with schistosomiasis, one with chronic alcoholism, and one with duodenal ulcer. In patients with scleroderma, schistosomiasis, and rheumatoid arthritis, an augmented precipitation of colloidal red might be expected because of the associated hyperglobulinemia. Again, patients with diabetes mellitus, thyrotoxicosis, and chronic alcoholism might have associated parenchymal cell damage. The abnormal colloidal red test in one patient with duodenal ulcer remains unexplained.

#### DISCUSSION

The biochemical mechanism responsible for the flocculation of the cephalin cholesterol, thymol, and colloidal red suspensions remains unexplained. In the absence of serum albumin, electrophoretically pure gamma globulin flocculates with the standard cephalin cholesterol reagent. The minimum quantity of gamma globulin necessary to produce precipitation is said to be between 0.22 and 0.11 milligram<sup>6</sup>. Kabat and co-workers<sup>7</sup> as well as Moore and associates<sup>8</sup> detected no difference between gamma globulin from normal or hepatitis sera. On the other hand, MacLagan and Bunn<sup>9</sup> found that hepatitis gamma globulin was more effective in flocculating cephalin cholesterol emulsions at a pH of 7.8 than normal gamma globulin. The sensitivities were 0.05 mg and 0.5 mg, respectively. They also found that a mixture of alpha and beta globulins from patients with hepatitis flocculated the cephalin cholesterol reagent while these

fractions from normal sera did not. Moore and co-workers<sup>6</sup> reported that inhibition of flocculation occurred when 5.9 mg of normal albumin were added to the reagent containing 0.33 mg of gamma globulin. A similar quantity of hepatitis albumin only reduced the flocculation from 4+ to 3+. MacLagan and Bunn<sup>7</sup> found that normal albumin was inhibitory to both normal and

hepatitis gamma globulin fractions in the proportion of 100:1. Thus, it appears that the flocculation of the cephalin cholesterol suspension depends mainly on some relationship between the gamma globulin and albumin fractions of the serum.

The mechanism responsible for the thymol turbidity reaction appears to be different. According to MacLagan and Bunn<sup>9</sup> and Recant, Chaigaff, and Hanger,<sup>10</sup> precipitation of the thymol reagent depends upon the presence of a lipid containing fraction of the serum. Cohen and Thompson<sup>11</sup> found by electrophoretic analysis that the thymol reagent precipitates beta globulin from both normal and hepatitis serum. MacLagan and Bunn<sup>9</sup> demonstrated that gamma globulin produced a faint turbidity when added to the thymol reagent, the turbidity increased markedly however when cephalin or lecithin was added. They found the turbidity abolished by normal but not by hepatitis albumin. Thus, although the thymol turbidity reaction involves primarily the beta globulin fraction of the serum there is some evidence that gamma globulin may also be involved but to a lesser degree.

Electrophoretic analysis of the serum proteins responsible for the precipitation of the colloidal red reagent has as yet not been reported, although such studies have been made on the colloidal gold reaction upon which this procedure is based. The gold sol like the cephalin cholesterol reagent, is precipitated by gamma globulin and the precipitation is inhibited by serum albumin.<sup>9</sup> Alpha and beta globulin mixtures have been reported to be even more inhibitory than albumin.<sup>9</sup> The present clinical study does not permit the formulation of any definite statement as to the possible mechanism responsible for the precipitation of the colloidal red suspension. It is interesting to note that this report includes several instances wherein the colloidal red test was definitely abnormal while the cephalin cholesterol and thymol turbidity reactions were within the normal range.

It should be emphasized that the tests used in this study are indicators of changes in the blood protein fractions. They mirror primarily alterations in gamma globulin and to a variable degree albumin and beta globulin. Because changes in these protein fractions are an accompaniment of hepatic disease, these tests are of value as indices of hepatic damage. Positive flocculation tests are not always the result of hepatic disease as noted in Table VII.

The fact that positive flocculation tests occur in hepatic disease only when the parenchymal cell is damaged makes them useful as an aid in the differential diagnosis of jaundice (see Tables II, III and VI). The colloidal red test like the cephalin cholesterol flocculation and thymol turbidity reactions is normal in early extrahepatic (major bile duct) obstruction i.e. before secondary damage to the liver cells has occurred by interference with bile flow.

In summary it may be stated that the colloidal red reaction is a sensitive test for determining alterations in the serum protein fractions resulting from damage to the parenchymal cells of the liver. Its technical simplicity recommends it for routine use. This statement does not imply that the colloidal red test should replace the other flocculation procedures. In fact, these tests supplement rather than supplant each other. Obviously the simultaneous performance of the three flocculation procedures described in this paper offers a

better panorama of the underlying alterations in the serum protein fractions than can possibly be surmised by the use of any single procedure alone<sup>12, 13</sup>

#### SUMMARY

1 A clinical evaluation of the colloidal red flocculation test is presented. In 122 subjects the test was compared with two other widely used procedures of a similar type, namely, the cephalin-cholesterol flocculation and thymol turbidity tests.

2 This study reveals that the colloidal red test is a sensitive and technically simple procedure for detecting alterations in the serum protein fractions accompanying hepatic disease. Its use as an aid in the differential diagnosis of jaundice is recommended.

# THE INFLUENCE OF DIBENAMINE UPON CIRCULATORY REACTIONS TO EPHEDRINE AND NEOSYNEPHRINE IN NORMAL MAN

WALLACE M. SHAW, M.D., L. M. PAPPER, M.D., AND E. A. ROVENSTINE, M.D.  
NEW YORK, N. Y.

ONE of the drugs most recently employed to produce blockade of the sympathoadrenal system is Dibenamine\* (dibenzyl  $\beta$  chloroethylamine). Nickerson and Goodman<sup>1</sup> have reported on its efficacy in preventing the vasopressor response to epinephrine and the excitatory response of smooth muscle to sympathetic nerve stimulation as well as to epinephrine in several organs of the body. They indicate, in addition, that the inhibitory effects of epinephrine are not influenced by the drug.

Different experimental methods have been employed to demonstrate the important protection that Dibenamine exerts against the cardiac effects of epinephrine in animals anesthetized with cyclopropane<sup>1, 2</sup> as well as those not subjected to anesthesia during the course of study.<sup>3, 4</sup> Although the site of action of this drug is not definitely established, the available evidence suggests that Dibenamine acts directly upon effector cells to prevent the responses to sympathin E and the excitatory manifestations of epinephrine.<sup>1, 5</sup>

Because of these interesting properties of Dibenamine, this study was undertaken to determine its effects on the actions of two commonly employed vasopressor drugs: ephedrine and Neosynephrin.

## METHODS

The vasomotor responses to ephedrine sulfate or Neosynephrin hydrochloride as manifested by changes in blood pressure, pulse rate, digital pulsations, and finger volume were measured in normal human subjects before and after Dibenamine administration, permitting each to act as his own control. Ephedrine was studied in this manner in three subjects and Neosynephrin in three others.

All tests were carried out approximately two hours after meal time in a dimly illuminated room at a temperature of 26 to 29° C. The subjects were observed in the supine position on a comfortable table after a slow intravenous infusion of physiologic saline solution had been started. Measurements of blood pressure were made by auscultation using a mercury sphygmomanometer with a pneumatic cuff applied to the right upper arm. The digital pulsations, pulse rate, and changes in finger volume were recorded on a Turner plethysmograph<sup>6, 7</sup> with the cup covering the distal phalanx of the left index finger.

A period of psychic and physical rest was allowed until the functions under observation had reached a steady state. These values for blood pressure and pulse rate are given in Table I. The absolute values for finger volume and amplitude of digital pulsations are of less importance.<sup>7</sup> Normally there are gradual variations in both these values. Changes to be significant should be sudden, reproducible, and related to known causes.

From the Department of Anesthesia, New York University College of Medicine and the Anesthesia Service, Bellevue Hospital.

Received for publication Feb. 2, 1949.

Dibenamine was supplied by Glaxo, Inc., Delaware, N. J. through the courtesy of Dr. W. Gump.

\*A Before the administration of Dibenamine B After the administration of dibenamine

†After a period of psychic and physical rest

Without the subject's knowledge the test drug, ephedrine (37 mg) or Neosynephrin (15 to 20 mg), was then injected intravenously and the effects were recorded. A day or two later Dibenamine hydrochloride applied as a 5 per cent solution in 50 per cent alcohol, was administered to the subjects in doses of 4 to 5 mg per kilogram of body weight in an infusion of 300 to 500 cc of physiologic saline solution over a period of thirty to eighty minutes. With rapid administration nausea was seen in Subject 3. One person (Subject 6) suffered a burning pain and tenderness along the course of the vein receiving the infusion until the Dibenamine was diluted to 600 cc and local heat was applied. Within three hours of the completion of the administration of Dibenamine the observations described were repeated. In Subject 2, observations were recorded only ten minutes after the completion of the Dibenamine infusion and the control series was performed nine days later.

### RESULTS

When ephedrine was given intravenously in the control series the blood pressure increased within thirty to sixty seconds reaching a maximum in three to six minutes. The systolic pressure increased 36 to 53 mm and the diastolic pressure 15 to 24 mm of mercury. Both returned to original levels within twenty minutes. Coincident with the highest blood pressure there was a reflex slowing of the pulse of 8 to 40 beats per minute. Then as the blood pressure fell, the pulse rate increased 8 to 15 beats above the original level gradually returning to normal. Subject 2 exhibited an irregular pulse rhythm characterized by pulsus alternans during the bradycardia. Finger volume was decreased by 0.03 to 0.07 cc within three minutes and gradually returned to the original size. The amplitude of digital pulsations was decreased by 0.005 to 0.011 cc per 5 cc of finger mass within three minutes after the ephedrine injection and returned to normal in ten minutes.

After Dibenamine had been administered the responses to intravenous ephedrine were reduced. The increase in systolic pressure was 10 to 30 mm and the diastolic pressure 0 to 16 mm mercury. No bradycardia was noted. There was an increase in pulse rate (4 to 18 beats per minute) within six minutes and it remained elevated for more than fifteen minutes. There were no episodes of pulse irregularity. In Subjects 1 and 3 the finger volume was decreased by 0.08 and 0.13 cubic centimeter. In Subject 2 there was a gradual increase in finger volume. The amplitude of digital pulsations decreased by 0.007 cc per 5 cc in Subjects 1 and 3 but remained unchanged in Subject 2. These results are epitomized in Table I.

In the control trials after Neosynephrin was given intravenously the systolic pressure was increased by 68 to 100 mm Hg within one to four minutes and the diastolic pressure increased 34 to 50 mm Hg in the same time. Both systolic and diastolic pressures returned to original levels in fifteen minutes. The pulse rate was decreased by 12 to 34 beats per minute coincidentally with the highest blood pressure. Only Subject 5 showed a secondary rise in pulse rate as the blood pressure fell. With the slowest bradycardia pulse irregularities consisting of extrasystoles were exhibited by Subjects 4 and 6. The finger volume was decreased by 0.22 cc and 0.07 cc in subjects 4 and 5 and returned to normal within five to eleven minutes. The amplitude of digital pulsations was decreased by 0.011 to 0.032 cc per 5 cc finger mass and returned to the original levels in eight to ten minutes.

After the administration of Dibenamine, Neosynephrin no longer produced such dramatic effects. The rise in systolic pressure was only 10 to 20 mm mercury. Diastolic pressure rose 10 and 8 mm Hg in Subjects 4 and 6 and fell 4 mm Hg in Subject 5. The pulse rate rose slightly in Subjects 4 and 5 but fell 18 beats per minute in Subject 6. There were no instances of irregular pulse rhythm. Finger volume did not change appreciably. The amplitude of digital pulsations decreased in Subjects 4 and 6 and increased in Subject 5. These results are summarized in Table I.

#### DISCUSSION

It will be seen that with the doses used, Dibenamine hydrochloride almost completely prevented the vasopressor effects of Neosynephrin. Peripheral vasoconstriction, as evidenced by a decrease in finger volume and decrease in the amplitude of digital pulsations, was minimized also.

The vasopressor effects of ephedrine were mitigated but not abolished by Dibenamine. Increases in blood pressure, while lower after Dibenamine, were still appreciable. Digital vasoconstriction in response to ephedrine was not prevented in two out of three trials (Subjects 1 and 3). In Subject 2, digital vasoconstriction was prevented by Dibenamine. An explanation may be found in the fact that the test was performed only ten minutes after the Dibenamine infusion had been completed.

These findings indicate the existence of different modes of action for ephedrine and Neosynephrin. Others<sup>1, 2, 3</sup> have demonstrated that Dibenamine completely abolished the pressor effects of epinephrine. Ephedrine, according to Gaddum,<sup>8</sup> acts by inhibiting amine oxidase, a ubiquitous enzyme, which destroys sympathin. The action of sympathin is thus potentiated. However, if the action of ephedrine was mediated through sympathin, Dibenamine should prevent its pressor actions. That it does not do so is evidence against this postulate.

Since the vasopressor and vasoconstrictor effects of ephedrine are not completely abolished by Dibenamine, ephedrine should be more effective than either epinephrine or Neosynephrin in producing these results in patients to whom Dibenamine has been administered.

#### SUMMARY

Circulatory responses to ephedrine and Neosynephrin were observed in man before and after the administration of Dibenamine hydrochloride.

The vasopressor and vasoconstrictor actions of Neosynephrin are almost completely prevented by Dibenamine. The vasopressor effects of ephedrine are decreased and the vasoconstrictor effects are not appreciably affected by Dibenamine.

After the administration of Dibenamine, Neosynephrin no longer produced such dramatic effects. The rise in systolic pressure was only 10 to 20 mm mercury. Diastolic pressure rose 10 and 8 mm Hg in Subjects 4 and 6 and fell 4 mm Hg in Subject 5. The pulse rate rose slightly in Subjects 4 and 5 but fell 18 beats per minute in Subject 6. There were no instances of irregular pulse rhythm. Finger volume did not change appreciably. The amplitude of digital pulsations decreased in Subjects 4 and 6 and increased in Subject 5. These results are summarized in Table I.

#### DISCUSSION

It will be seen that with the doses used, Dibenamine hydrochloride almost completely prevented the vasopressor effects of Neosynephrin. Peripheral vasoconstriction, as evidenced by a decrease in finger volume and decrease in the amplitude of digital pulsations, was minimized also.

The vasopressor effects of ephedrine were mitigated but not abolished by Dibenamine. Increases in blood pressure, while lower after Dibenamine, were still appreciable. Digital vasoconstriction in response to ephedrine was not prevented in two out of three trials (Subjects 1 and 3). In Subject 2, digital vasoconstriction was prevented by Dibenamine. An explanation may be found in the fact that the test was performed only ten minutes after the Dibenamine infusion had been completed.

These findings indicate the existence of different modes of action for ephedrine and Neosynephrin. Others<sup>1, 2, 3</sup> have demonstrated that Dibenamine completely abolished the pressor effects of epinephrine. Ephedrine, according to Gaddum,<sup>8</sup> acts by inhibiting amine oxidase, a ubiquitous enzyme, which destroys sympathin. The action of sympathin is thus potentiated. However, if the action of ephedrine was mediated through sympathin, Dibenamine should prevent its pressor actions. That it does not do so is evidence against this postulate.

Since the vasopressor and vasoconstrictor effects of ephedrine are not completely abolished by Dibenamine, ephedrine should be more effective than either epinephrine or Neosynephrin in producing these results in patients to whom Dibenamine has been administered.

#### SUMMARY

Circulatory responses to ephedrine and Neosynephrin were observed in man before and after the administration of Dibenamine hydrochloride.

The vasopressor and vasoconstrictor actions of Neosynephrin are almost completely prevented by Dibenamine. The vasopressor effects of ephedrine are decreased and the vasoconstrictor effects are not appreciably affected by Dibenamine.

technique is that the end point is completely subjective and will vary with different observers, although for each observer a normal range can be secured. A more objective technique utilizing radioactive gas, is being investigated. However, the present method has the advantage of not requiring any special apparatus or training and can be used at the bedside by the general practitioner.

GROSS PORTAL CIRCULATION TIME IN FIVE GROUPS OF PATIENTS

Fig 1

## RESULTS

In thirty four normal controls and three compensated cardiac subjects the gross portal circulation time ranged between 11 and 25 seconds. The span in seven decompensated cardiac subjects and in one clinically compensated cardiac patient was between 32 and 65 seconds. Seven patients with Laennec's cirrhosis with clinical evidence of portal hypertension evinced by either melena or ascites but without evidence of cardiac failure gave measured times between 34 and 180 seconds.

A group of fourteen cases of miscellaneous types of hepatic disease were studied. None of these subjects had melena or ascites or cardiac failure but all showed hepatic hypofunction by the usual liver function tests. Half of these subjects presented gross portal circulation times lower than 25 seconds, while the remaining seven had prolonged times between 27 and 65 seconds. This latter group may represent cases of portal hypertension without clinical manifestations. Prolonged gross portal circulation time due to heart failure can be readily differentiated from that of portal cirrhosis by the prolonged arm-to-tongue circulation time in the former.

#### SUMMARY

A simple method for the quantitative estimation of portal circulation time is described.

# ACTINOMYCES BOVIS IN TISSUES AND BODY FLUIDS

PHILIP SCHAIN D SC, ANNE DE STEFANO B A, AND JOSEPH P KAZLOWSKI, B S  
STATEN ISLAND, N Y

## INTRODUCTION

THIS work is being presented to show the incidental finding of *Actinomyces bovis* in diseases other than actinomycosis. The study was prompted by the discovery of *A. bovis* in a bone marrow aspiration from a suspected case of brucellosis which was determined later to be Hodgkin's disease. Consequently, various materials such as blood and bone marrow, from all subsequent cases of Hodgkin's disease, brucellosis or related syndromes were cultured for this organism. Routine bone marrow aspirations from patients with various blood dyscrasias were cultured as controls. *A. bovis* was recovered from specimens of seven patients. The presence of this organism in the bone marrow or blood of individuals suffering from a disease other than actinomycosis has not previously been reported.

We are prompted to publish this preliminary report because of the scarcity of proper material for study at this institution. Further investigation at this and other laboratories will test the value of our findings.

## METHODS

The media used were products of Difco and consisted of brain heart infusion, Tryptose broth, Tryptose phosphate broth and thioglycollate broth. The latter was distributed in 20 c.c. quantities in tubes and the others in 60 c.c. quantities in flasks.

Inoculation of media with the body fluids and tissues was as follows. Bone marrow: Two milliliters of bone marrow were added to 3 ml. of 2.5 per cent sodium citrate in distilled water. One milliliter of this mixture was added to each of the flasks of different media and 0.5 ml. to each of two tubes containing thioglycollate broth. Blood: Fifteen milliliters of blood were added to 3 ml. of 2.5 per cent sodium citrate solution and of the mixture 4 ml. quantities were added to the flasks of different media and 1 ml. to each of two tubes of thioglycollate broth. All other specimens were inoculated *ad libitum*.

Incubation was carried out at a temperature of 37° C. The brain heart infusion cultures were kept in the normal atmosphere and the Tryptose broth cultures (for cultivation of *Brucella abortus*) were maintained in an atmosphere of increased carbon dioxide. Specimens inoculated into the Tryptose phosphate broth were grown under anaerobic conditions. Of the two tubes of thioglycollate broth seeded with each specimen one was grown in an anaerobic atmosphere and the other in an atmosphere of increased carbon dioxide.

## CASE HISTORIES

CASE 1 (No. 4328) — A clinical problem diagnosed as brucellosis. The Brucellergen skin sensitivity reaction and the brucella agglutination tests were negative initially but the latter became positive (1 to 640) after the skin test and subsequent vaccination with brucella antigen. Eleven specimens of blood, one of bone marrow and one of spinal fluid were cultured for brucella and other organisms. Of these one blood culture, the bone marrow specimen, and the spinal fluid showed *A. bovis*. The diagnosis of Hodgkin's disease was made on necropsy findings.

From the Laboratory Service of the Veterans Administration Hospital.

Published with permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

Received for publication Feb. 7, 1949.

CASE 2 (No 8739) —Brucellosis and Hodgkin's disease were the diagnoses considered. Agglutination tests for brucella were negative. Twelve specimens of blood, two of bone marrow, one liver biopsy specimen, four sputa, and one sample of gum scrapings were cultured. Of these, *A. bovis* was recovered from one blood specimen, the two bone marrow samples, and the liver biopsy. The final clinical diagnosis of Hodgkin's disease was confirmed by the liver biopsy.

CASE 3 (No 8823) —Clinically diagnosed as Hodgkin's disease, confirmed histologically. One specimen of blood and one of bone marrow were cultured, the latter showing the presence of *A. bovis*.

CASE 4 (No 8635) —An ophthalmologic problem, diagnosed as nummular keratitis, most probably due to brucellosis. Brucella agglutination, Brucellergen skin test, and opsonic index failed to confirm Brucella as the etiologic factor. Two blood specimens, two bone marrow aspirations, and corneal scrapings were bacteriologically studied. *A. bovis* was recovered from the two bone marrow aspirations and the corneal scrapings.

CASE 5 (No 9340) —Clinical diagnosis of xanthoma tuberosum. In the routine study of bone marrow, a culture also was done and *A. bovis* was recovered.

CASE 6 (No 9936) —Clinically diagnosed as abdominal granuloma. Culture of a bone marrow aspiration revealed the presence of *A. bovis*.

CASE 7 (No 9912) —Clinically diagnosed as Hodgkin's disease, confirmed histologically. The culture of bone marrow aspiration showed *A. bovis*.

*A. bovis* was not found in the single bone marrow samples of two patients with clinically diagnosed and histologically confirmed Hodgkin's disease.

Six patients with various blood dyscrasias, requiring bone marrow studies, were used as controls. Their bone marrow was cultured as described, with negative results.

#### RESULTS AND SUMMARY

*A. bovis*, in pure culture, was isolated from the body fluids and tissues of four patients with proved cases of Hodgkin's disease, from one with a disease associated with brucellosis, from one diagnosed clinically as having abdominal granuloma, and from one with xanthoma tuberosum.

From this group, the organism was recovered in nine out of nine bone marrow aspirations, two of the twenty-four samples of blood, and from the spinal fluid, liver biopsy section, and corneal scrapings.

*A. bovis* was not found in the single bone marrow samples taken from two proved cases of Hodgkin's disease and from six patients with blood dyscrasias, or from more than 1,000 samples of blood and approximately 7,500 other specimens grown in the same fashion as described during this investigation.

Earliest and most consistent growth was seen in the thioglycollate broth incubated in a carbon dioxide atmosphere and in Tryptose phosphate broth grown under anaerobic conditions. Growth occurred at an average of six days in both media.

This work is being published to present the incidental finding of *A. bovis* in diseases other than actinomycosis. It is not the intention of the authors to indicate that *A. bovis* is the causative agent of any disease other than actinomycosis. The finding of this organism in the tissues and body fluids of patients who have granulomatous diseases is provocative. It is entirely possible that if other disease entities were investigated, similar findings might result.

Patients not having clinical actinomycosis may harbor *A. bovis* in their mouths, teeth decay, and mucous membranes, whence it is feasible that the organism, under favorable conditions may enter the blood stream. Since *A. bovis* has been found repeatedly over several months of observation in the same patients it does not seem to be merely a transient invader. The obvious disturbance of the reticuloendothelial system in granulomata may render a patient more susceptible to a chronic bacteremia with involvement of the tissues and body fluids.

Serologic as well as further bacteriologic studies are being carried out as material becomes available.

Grateful acknowledgment is made to Dr. N. F. Conant, of Duke University, and Major P. R. Carlquist and Major L. R. Kuhn, of the Army Medical School, for confirming the identity of the organisms.

## DEUTERIUM OXIDE AND THIOCYANATE SPACES IN PROTEIN DEPLETION

V HOLLANDER, M D , P H D , \* P CHANG, M S , AND Co TUI, M D  
NEW YORK, N Y

PREVIOUSLY, the partition of body fluid between the extracellular and intracellular spaces has been attended by indirection and assumption<sup>1, 2</sup> This type of approach has shown the importance of such data in understanding the distorted electrolyte and fluid balance in such clinical conditions as diabetic acidosis<sup>3</sup> and infantile diarrhea<sup>4</sup> The simultaneous determination of total body water and extracellular fluid volume theoretically gives the intracellular fluid volume by difference without the assumptions which have been necessary in the past

Total body water has been measured by desiccation in the human being<sup>5</sup> and values of 58 to 67.6 per cent of the body weight have been obtained The technical difficulties of such a procedure are easily appreciated and the method is of course worthless for clinical investigation The ideal method is to use a tracer substance which will be everywhere in equilibrium with body water Sulfanilamide was for a time used for this purpose, and it gives values of the correct order of magnitude<sup>6, 7, 8</sup> Urea<sup>9, 10</sup> and thiourea<sup>11, 12</sup> have been tried Apparently none of these three substances distribute themselves equally and exclusively in the body water Since it has been shown that in normal adults of many mammalian species fat is a diluent and water is a relatively constant portion of the lean body mass,<sup>13</sup> it has been suggested that an independent method for total body fat be established and water determined from this relationship The specific gravity method for total body fat has been used for this purpose<sup>14, 15</sup> and results of reasonable magnitude have been obtained One of the best theoretical approaches to this problem, the simultaneous determination of body fat and water through differential solubilities of gases in body tissue,<sup>16</sup> has been neglected from the experimental point of view The best data on total body water in man comes from isotopic measurements Hevesy and Hofer<sup>17</sup> first used deuterium oxide in man Using oral administration, they got a value of 63 per cent of body weight Moore obtained a value of 72.5 per cent in a human subject<sup>18</sup> Pace<sup>19</sup> obtained a value of 64.7 per cent of body weight in a human subject, using tritium oxide We decided to use deuterium oxide as a tracer for total body water, although when T<sub>2</sub>O of higher activity becomes available and simpler techniques for its measurement are developed it may well provide a better method

Though many methods are in vogue for measuring extracellular fluid volume none at present seems satisfactory. Thiocyanate is rapidly distributed, is easy to determine chemically, and has a slow rate of urinary excretion. On the other hand, it enters the red blood cells and is secreted by several digestive glands. Most studies with thiocyanate in normal men give values of from 20 to 28 per cent of the body weight<sup>20, 21</sup>. Sucrose has the advantage of not being an electrolyte, and therefore correction for Donnan effect is unnecessary. Sucrose is excreted so rapidly in the urine that an accurate measure of sucrose space is difficult. The sucrose space<sup>21</sup> appears to be 17 to 20 per cent of the body weight<sup>22</sup>. Radiosodium and thiocyanate spaces have been compared in man<sup>23</sup>. In normal men the sodium space (corrected for sodium which has penetrated bone) is 21.1 per cent of body weight and thiocyanate space, 23.5 per cent of body weight. In another study thiocyanate space was compared with radiosodium and radiochloride space<sup>21</sup> in the dog. Here the volumes of distribution of  $\text{CNS Na}^+$  and  $\text{Cl}^-$  were 36.20 and 25 per cent respectively of the body weight. Thus the dog may show dissociation between the values for extracellular space determined by thiocyanate space and by other techniques<sup>24</sup>. Thiocyanate, sucrose, and sulfate ion have approximately the same volume of distribution<sup>1</sup>. Bromide has been used as a measure of chloride space<sup>2</sup>. Further doubt has been cast on the thiocyanate space as a true representation of extracellular fluid volume since in malaria, spotted fever, and bacteremia<sup>18</sup> it may approach the value of total body water. In normal individuals, one might feel certain that at least the order of magnitude of the thiocyanate space was correct for extracellular fluid volume because of the concordance in volumes of distribution of the several substances cited; but, in the nephrectomized rabbit, thiocyanate distributes itself in a volume of 30 per cent of the body weight while inulin—a substance which is known not to enter the red cell, nor to be secreted by digestive glands, nor to suffer any binding to plasma protein—has a volume of 20 per cent<sup>2</sup>. Inulin might well be the ideal substance to measure extracellular fluid volume, but a method will have to be developed to circumvent its rapid urinary excretion. In spite of these difficulties in interpretation of thiocyanate space values we have routinely used them in this work although we are at present critically evaluating the thiocyanate space in patients showing abnormalities in water metabolism.

This study of human beings is divided into three parts: a study of two normal subjects, three cases of protein depletion, and a rather detailed study of the rehabilitation of two cases of protein depletion by the use of very high protein intakes of the order of magnitude referred to as 'hyperproteinization' in this laboratory<sup>25</sup>.

Hereinafter the thiocyanate space will be designated  $\text{SCN S}$ , the per kilogram thiocyanate volume,  $\text{SCN S/W}$ , the total body water,  $\text{TBW}$ , and the per kilogram body water,  $\text{TBW/Wt}$ .

#### METHOD

$\text{SCN S}$ <sup>1</sup> nitrogen balance, and general metabolism techniques were carried out as described previously from this laboratory<sup>2</sup>.  $\text{TBW}$  was measured using

deuterium oxide as tracer. A carefully measured volume of 99.8 per cent of heavy water was delivered slowly from a burette attached to an intravenous needle and a quantity injected sufficient to bring the concentration of  $D_2O$  in the body fluid in the range of between 0.1 per cent and 0.2 per cent. Ten milliliter samples of blood were drawn at one, two, and three hours following injection of  $D_2O$ . If the patient had had previous injections of heavy water, an initial 10 ml sample of blood was necessary as a blank. The  $D_2O$  concentration reached equilibrium in less than an hour, confirming a similar observation of Moore.<sup>18</sup> The three samples of blood may thus be treated essentially as triplicates. The blood was transferred to 125 ml flasks equipped with ground-glass joints which were promptly stoppered. The blood was then frozen as a film in the inside surface of the bulb by rotating the flask slowly in a Dewar flask filled with crushed dry ice. No organic liquid was ever mixed with the dry ice to form a freezing mixture, and organic vapors in the laboratory were scrupulously avoided to prevent contamination of the water samples. The flasks were rapidly attached to a vacuum distillation apparatus such that the water which was lyophilized from the blood was condensed in a trap cooled by dry ice. This water was purified by a modification of the method of Keston and co-workers.<sup>30</sup> Both the samples and the standards were passed through an electric furnace in an atmosphere of liquid air oxygen in order not only to oxidize the organic impurities present, but also to adjust the  $O^{18}/O^{16}$  ratio from that of "water" oxygen to that of "air" oxygen.<sup>31</sup> The water was then distilled from 15 ml flasks attached by means of ground-glass joints to a small condenser. The samples were distilled after adding a few crystals of potassium permanganate and a tiny fragment of dry potassium hydroxide. Since at this stage the volume of the water is 5 ml, one need not fear deuterium exchange with the replaceable proton of the alkali. An arbitrary middle fraction was collected from this distillation in 10 ml glass stoppered weighing bottles. (This distillation is best not done on humid days.) The concentration of the deuterium was then determined by a modification of the falling drop method of Keston, using instead of the mercury filled capillary pipette which has hitherto been used by other workers, a constriction pipette of the type described by Levy.<sup>32</sup> This pipette has the advantages of great reproducibility, ease of construction, and freedom from the ever-present danger of air leaks which can occur with the mercury column pipette. The one-, two-, and three hour samples show an average deviation from the mean of 3 per cent. Times of fall, in the concentration range of 0.1 to 0.2 per cent,  $D_2O$ , agreed on an average of 0.2 second (or 0.002 per cent,  $D_2O$ ). Temperature was controlled to  $\pm 0.01^\circ C$ .

#### EXPERIMENTAL SUBJECTS

The normal subjects, H and T, were members of our own research team (Table I). The four depleted subjects, D, F, B, and C, were patients in the metabolic ward of the Third Surgical Service of the Bellevue Hospital. D and F had carcinoma of the tongue and granuloma of the sigmoid respectively. In these two only initial determinations were made. In both B and C, serial determinations were performed during different phases of repletion. Abstracts of the histories of these last two subjects appear below.

TABLE I TOTAL BODY WATER AND RELATED VALUES OF TWO NORMAL AND FOUR DEPLETED SUBJECTS

SUBJECT	WT (KG)	SCN S (LITERS)	SCN S INTERALG (CC)	TBW (LITERS)	TBW % WT	IW (TBW CNS) (LITERS)	TBS (WT TBW) (KG)	IW/ TBS

SCN S sodium thiocyanate space

TBW total body water

IW intracellular water

TBS total body solids

*Subject B*—A 39 year old colored man whose premorbid weight was 71.0 kilograms had swallowed live in a suicidal effort on April 6 1947. Prompt emergency treatment was given, but an esophageal stricture developed and on July 8 his weight was 53 kilograms, total plasma proteins were 6.25 Gm per cent Hgb 11 Gm per cent and RBC 3,950,000. On July 19 gastrostomy was done and the patient was hyperalimentated through the gastrostomy opening in an effort to restore the nutritional status. His gain in weight and strength was quite satisfactory as can be seen in Table I and on November 13 he weighed 59.3 kilograms, had improved greatly in strength and the plasma proteins were 6.8 Gm per cent, Hgb 13.8 Gm per cent and RBC 4,400,000. On June 15 1948 a transthoracic esophageal resection was done with closure of the gastrostomy.

*Subject C*—A 53 year old Chinese man whose premorbid weight had been 66.5 kilograms was admitted to Bellevue Hospital Psychiatric Service July 7 1947 after he made a suicidal effort at another hospital where he had undergone laparotomy for duodenal ulcer with bleeding. At that time Hgb was 4.7 Gm per cent RBC 1.17 million and 2+ ankle edema was present. On transfusion of blood and administration of protein hydrolysate the patient became rational and was up and about the ward on July 20. On August 19 an infradiaphragmatic vagotomy with gastroenterostomy was done and the patient was sent to the metabolic ward to be rehabilitated since his weight was 35.9 kilograms. D, F, B and C had lost 36, 38, 28, and 36 per cent of body weight.

## RESULTS

An example of the reproducibility of results obtainable with the method of determining TBW is seen on examination of the data obtained from the normal subjects H and T.

H had a total body water of 55 per cent of his body weight. If the concept of lean body mass<sup>5</sup> is correct, and 73.2 per cent of this man's lean mass is water, then lean mass is 68.3 kg, and his fat content 22.7 kg, or 25 per cent of body weight. His moderate obesity explains his somewhat low water content.

The extracellular fluid volumes for H and T were 21.7 and 21.1 respectively. The ratios of thiocyanate space to weight (CNS/W) were 238 and 292 ml per kilogram. It will be noted that the thiocyanate space represents 43.4 and 50 per cent of total body water.

As may be seen in Table I, all of the depleted subjects showed expanded SCN-S at the initial test, the initial per kilogram values all being over 400 cc, and the ratio SCN-S/TBW being 66.3, 61.4, 56.2, and 62 respectively, while in the two normals the corresponding values were 50 and 42.4. This expansion of the SCN-S has been reported by other workers, among whom must be mentioned Lyons,<sup>33</sup> Mollison,<sup>34</sup> Walters and associates,<sup>35</sup> Henschel and associates,<sup>36</sup> and Co Tui and co-workers.<sup>28</sup>

The ratio TBW/Wt is also worth noting. In the two normal subjects this value was 0.550 and 0.585. In the four depleted subjects (D, F, B, and C) this ratio ranged from 0.655 to 0.730.

If the SCN-S were a faithful representative of the extracellular space, it would be possible to calculate the degree of hydration of the intracellular compartment. This could be achieved by obtaining two factors: (a) the total body solids, TBS, by subtracting the weight of the TBW from the body weight, and (b) the intracellular water, IW, which can be obtained by subtracting the extracellular volume from the TBW. The ratio IW/TBS would represent the hydration of the intracellular compartment, assuming that all but a negligible portion of the body solids were in the intracellular compartment. While fully aware that it may be premature at this point to assign any value to this ratio, one is nevertheless tempted to attempt some speculation in this direction. The IW/TBS ratios in the two normal subjects were 0.69 and 0.71. In three of the depleted subjects (F, B, and C), the corresponding values were 1.19, 1.18, and 0.82 respectively. In D it was 0.65. If these values were in fact correct, they would suggest an inconstant state of intracellular hydration in protein depletion. In view of the great variability of the plasma volume, body weight, and clinical edema demonstrated in protein depletion by Denz,<sup>37</sup> this possibility would be interesting to follow up in future studies.

TABLE II. PREMORBIDITY AND PRESENT TOTAL BODY SOLIDS OF DEPLETED SUBJECTS

SUBJECT	IPREMORBIDITY WT (KG)	WEIGHT LOSS (%)	TBS <sub>1</sub>	TBS	PER CENT TBS LOSS
D	73.9	36	29.56	16.2	48
F	71.8	38	28.76	10.9	62
B	70.4	28	28.16	13.7	51
C	61.4	36	24.56	12.4	49

TBS<sub>1</sub>, premorbidity TBS (estimated)

In Table II the premorbidity total body solids TBS<sub>1</sub> computed as 40 per cent of the weight of the four depleted subjects are set forth against their present total body solids, TBS calculated from the present body weight and the determined total body water. It will be seen that the percentage fall in body solids was in every case higher than the percentage fall in body weight and that in one subject, F, this fall was as high as 62 per cent. If this type of calculation

is valid, this means that 68 per cent of the subject's body substance has been lost. In this connection, it is significant that in the subjects B and C in whom serial determinations were made during repletion the values of TBS rose consistently as repletion progressed and that TBW/Wt, IW/TBS, and SCN S/W dropped.

It would also be of interest to gain an approximate knowledge of the state of total body fat both in depletion and during repletion. Since severely ill patients may not tolerate the procedure of total body fat determination by specific gravity method, one may make an approximation of this value by assuming a constant relationship between lean body mass and total body water in the normal individual as done by Pacc and co-workers<sup>19</sup>.

One may assume that subject B was 'normal' on November 13. His lean body mass may then be computed since, according to this concept,  $0.732 \times \text{lean body mass} = \text{total body water}$ . This would give a lean body mass of 48 kg at this time or a total fat of 11.3 kg, which would amount to 19.1 per cent of the total body weight.

From the period September 5 to November 13 B retained about 1,100 Gm of N or 6.9 kg of protein. The total weight gain was 8.6 kg, and total body water decreased by 2 kilograms. Since the gain in total solids was therefore 10.6 kg, 3.7 kg of fat must have been formed during this period. From this gain of 3.7 kg in fat we can reason that on September 5 the total fat was 7.6 kg or 14.9 per cent of body weight at that time.

Our nitrogen retention data on subject C are not complete enough to warrant estimation of changes in fat and protein content.

Such calculations make one increasingly aware of the desirability of an independent method for measuring total body fat. During the process of repletion, the water content of the body expressed as a percentage of body weight is influenced by the loss of extracellular fluid, the retention of nitrogen the presumptive retention of water which should occur with nitrogen retention to form muscle, and the gain in fat. These are factors which have been well evaluated in the crease analysis studies of Benditt and associates<sup>38</sup> in the rat, but which remain difficult problems in the human being.

In our work we were not able to observe the retention of water corresponding to nitrogen retention. In order to preserve osmotic equilibrium it is required that 3 Gm of water be returned for every gram of protein formed but actually it appears that in the process of depletion, protein may be lost at a faster rate than water, and it may well be that the partially ionized potassium compounds which have been postulated as occurring in intracellular water defend the osmotic integrity of the cell by further dissociation when protein is lost.

#### COMMENTS

This preliminary work is being reported because to our knowledge it is the first attempt of its kind in the study of the body compartments and constituents in protein depletion. It has already demonstrated that there is a profound

disturbance in both the body constituents and compartments in protein depletion, disturbances which have been assumed heretofore but have not been susceptible of direct measurement. The disturbance in water metabolism does not seem to be in the SCN-S alone, but seems also to extend to the intracellular compartment as well.

We wish to thank Dr A S Keston of the Department of Biochemistry, New York University Medical School, for his interest in and helpful advice throughout the course of this work.

Grateful acknowledgment is made of the allocation of deuterium oxide by the Atomic Energy Commission.

## PARENTERAL NUTRITION

### VIII THE VASODEPRESSOR ACTIVITY OF SOYBEAN PHOSPHATIDE PREPARATIONS

ROBERT P. GEYER, PH D, DONALD M. WATKIN, M D,  
LEROY W. MATTHEWS, B S, AND FREDRICK J. STARE, M D  
BOSTON, MASS

IN PREVIOUS reports from this laboratory the preparation and use of emulsions of fat for intravenous nutritional purposes have been described<sup>1,2</sup> Various emulsions containing soybean phosphatides as the stabilizer have been given successfully to the rat, dog, and rabbit. It was clearly shown in these studies that fat given in this manner is well utilized for energy. More recently, studies using fat labeled with C<sup>14</sup> have confirmed the utilization of fat in emulsions given intravenously.<sup>3,4</sup>

The only adverse physiologic effects which were evident when fat emulsions were given to dogs intravenously were occasional nausea, vomiting, and excessive salivation when the initial infusions were given too rapidly and a moderate normocytic anemia<sup>5</sup> if the fat infusions were continued for a period of two to three weeks or longer. The anemia rapidly disappeared, however, when the infusions were discontinued. Measurements of the blood pressure of dogs by an ordinary sphygmomanometer disclosed no significant alterations from normal. However, in a few preliminary observations in man following the intravenous injections of these fat emulsions, a fall in arterial blood pressure occasionally resulted. Before continuing with clinical studies, observations were undertaken in which the cat was used in order to obtain more information on this vasodepressor phenomenon. The experiments reported in this paper were designed to (1) determine the origin and character of the vasodepressor activity, (2) compare more rigorously the species variation with respect to the vasodepressor action, and (3) investigate possible methods of removing the vasodepressor substance.

#### EXPERIMENTAL

##### *Methods—*

1 Measurement of arterial blood pressure was done in the usual manner. The carotid artery of the anesthetized (Nembutal) animal was cannulated and by means of a citrate filled system was connected to a mercury manometer provided with a moving stylus. Recordings were made on a smoked paper drum attached to a kymograph. In many cases, concurrent pneumograph recordings were also taken.\*

2 Injection of the test substance was done as follows. A glass cannula was inserted into the femoral vein and by means of a narrow bore rubber tube was connected to a

Received for publication Jan. 27, 1949.

\*The authors wish to express appreciation to Dr. E. M. Landis, Department of Physiology, Harvard Medical School, and Dr. J. L. Whittenberger, Department of Physiology, Harvard School of Public Health, for advice and the loan of apparatus used in these studies on blood pressure.

burette which contained either 0.9 per cent sodium chloride or 5 per cent dextrose solution. The test material was injected from a suitable syringe through a short No. 24 needle which was inserted as far as possible through the rubber tube close to the cannula. Immediately after the injection and before withdrawal of the needle 1 to 2 ml of the solution from the burette were allowed to run in as rapidly as possible. The syringe was then quickly withdrawn.

3. Emulsification of the test material usually was accomplished in one of the following ways: (a) stirring with a wire stirrer at 4000 rpm and 90° C for four to seven minutes; (b) blending in the Waring Blendor at high speed and at 70 to 90° C for one to five minutes; and (c) first blending as under (b) and then homogenizing in a high pressure homogenizer\* under nitrogen at 3000 to 4000 psi and 85 to 90° C for five to fifteen minutes. Where modifications of these methods were used the changes are indicated. Tonicity was achieved by the addition of saline or dextrose to give a final concentration of 0.9 and 5 per cent respectively. Adjustment of pH was accomplished with disodium phosphate.

4. The fat emulsifying properties of the various fractions of soybean phosphatides were determined in the following manner. One liter of an aqueous mixture containing 3 per cent of the phosphatide fraction 15 per cent coconut oil and 47 per cent dextrose was homogenized under high pressure by the technique previously described<sup>6</sup> but using the homogenizer referred to in the preceding paragraph. Disodium acid phosphate was used when necessary to adjust the pH. When the resulting emulsion was of fine particle size as judged by microscopic examination a sample was autoclaved and again examined for particle size.

*Origin and Character of the Vasodepressor Action and Variation Between Species*—Preliminary blood pressure measurements on the cat indicated that for this species a marked decrease in pressure occurred when even small quantities of an emulsion (Emulsion 35)<sup>1</sup> containing 3 per cent of a purified soybean phospholipid fraction were injected rapidly. This emulsion contained coconut oil 15 per cent fraction B(F 2) 3 per cent dextrose 47 per cent and water 80 per cent (weight/volume). It was readily apparent that a greatly decreased response resulted when a given dose was administered for the second time even though as much as thirty minutes elapsed between the two injections. To determine whether or not the soybean phosphatide stabilizer fraction B(F 2)<sup>1</sup> was responsible for the vasodepressor activity of the fat emulsion a 3 per cent emulsion of this material was prepared by high pressure homogenization made isotonic to rat serum with dextrose and autoclaved for fifteen minutes at 15 psi in a pressure bottle filled with nitrogen. Small quantities of this preparation were injected into a cat and the depressor response was found to be similar to that obtained when Emulsion 35 was administered.

Blood pressure studies were undertaken using the dog, rabbit and rat as test animals in addition to the cat. All blood pressure recordings were taken in a manner similar to that used for the cat with the exception of the rat. For this species it was necessary to use a capillary manometer and record the pressure changes visually. Neither the fat emulsion (Emulsion 35) nor the 3 per cent emulsion of the phosphatide fraction B(F 2) was effective in lowering the blood pressure of the rat rabbit or dog more than 15 mm even when large quantities were injected as rapidly as possible. Table I shows a typical response obtained with the cat, dog, rabbit and rat to the injection of a blended 6 per cent preparation of the phosphatide fraction B(F 2). It is readily apparent

\*Manton Gaulin Homogenizer Model No. 75 CGD Manton Gaulin Manufacturing Company Inc. 44 Garden Street Everett 49 Mass.

that the cat is far more susceptible to the depressor activity and hence in all subsequent testing for vasodepressor activity the cat was used

TABLE I RESPONSE OF VARIOUS SPECIES TO THE VASODEPRESSOR PRESENT IN PHOSPHATIDE FRACTIONS MADE FROM COMMERCIAL SOYBEAN PHOSPHATIDES

SPECIES	BODY WEIGHT (GM)	MATERIAL INJECTED	VOLUME INJECTED (ML)	WEIGHT OF FRACTION INJECTED (MG/KG B.W.)	BLOOD PRESSURE RESPONSE	
					DECREASE (MM)	INCREASE (MM)
Rat	225	Blended 6% fraction B(F 2)	1.0	277	—	—
		Blended 6% fraction 70 f	2.0	554	14	—
Rabbit	3,100	Blended 6% fraction B(F 2)	2.0	39	—	4

Cat	1,500	Blended 6% fraction B(F 2)	0.1	4	56	24
		Blended 1.2% fraction 70 f	0.1	0.8	46	—

Since it was evident that the phosphatide preparation B(F-2) contributed the vasodepressor activity, a number of the precursors of this fraction were investigated to determine whether the depressor was present originally in the soybeans or was introduced at some point during the process of manufacture. The following materials were tested in the cat for vasodepressor activity:

1 Freshly prepared soybean phosphatides obtained by extracting 25 kg quantities of ground dried soybeans for four successive three hour periods with 3 liter portions of boiling redistilled petroleum ether. The combined extracts were concentrated in vacuo to a volume of approximately 200 ml and 12 liters of anhydrous acetone were added and the mixture was allowed to stand overnight. After decantation of the clear supernatant liquid, the residue was dissolved in 40 to 50 ml of ether, filtered, and poured into 500 ml of acetone. The precipitate was filtered off after standing for three hours and was then dried in vacuo at room temperature. A 15 per cent emulsion of this material was prepared by the stirring technique, with dextrose present for tonicity, and examined for depressor activity.

2 An autoclaved portion of the 15 per cent emulsion of the freshly prepared soybean phosphatides.

3 Freshly prepared soybean phosphatides which had been allowed to stand in air for four days at room temperature and which were then emulsified at a 3 per cent concentration using the stirrer technique. Dextrose was added for tonicity.

4 Fat emulsion stabilized with freshly prepared soybean phosphatides and prepared by using the homogenization procedure described previously.<sup>6</sup> The emulsion contained 15 per cent refined corn oil, 2 per cent freshly prepared soybean phosphatides, 5 per cent dextrose, and water.

5 Commercial Liquid Lecithin\* emulsified at a 6 per cent concentration by the blender technique with dextrose present. This emulsion was not entirely stable and, therefore, only the portion which remained in true dispersion was used in the vasodepressor tests.

6 Asolectint (commercial soybean phosphatides) emulsified by the blender procedure at a 6 per cent concentration using dextrose for tonicity.

7 Emulsion 35<sup>1</sup>.

8 Soybean phosphatide fraction B(F 2)<sup>1</sup> prepared in a 3 per cent emulsion by the high pressure homogenizer method using dextrose for tonicity.

9 Soybean phosphatide fraction B(F 2) prepared in a 6 per cent emulsion by the high pressure homogenizer method using dextrose for tonicity.

\*Refers only to the initial response

†In each case the blood pressure had returned to normal prior to the injection

These preparations were injected into cats as described earlier, and blood pressure recordings were taken. In addition, Preparation 9 was injected several successive times into a cat to test for tachyphylaxis. The results, together with pertinent data are given in Table II. It is seen that the depressor activity is primarily in the phosphatide preparations but is not present in freshly prepared material, even after autoclaving. Repeated injections of the phosphatide material result in greatly decreased vasodepressor responses. Fig 1 shows a typical response obtained with the cat to the repeated injection of a blended 6 per cent preparation of the phosphatide fraction B(F 2).

While the experiments already described were in progress, other experiments were concurrently undertaken for the purpose of fractionating the commercial soybean phosphatide preparation known as Asolectin and the phosphatide fraction prepared from it known as fraction B(F 2) from two stand points, namely, (1) to prepare if possible, a depressor free phosphatide fraction which would still be a suitable emulsifying agent and (2) to concentrate the vasodepressor substance(s) and determine some of its characteristics.

The initial studies were made on phosphatide fractions already on hand. These fractions had been prepared some months earlier in connection with fractionations of Asolectin designed to remove the material which had caused the granulomatous lesions reported in earlier work<sup>1</sup> and had been stored at -8° C during the ensuing months. The preparation of fractions A(F 1), B(F 1), and C(F 1) have been reported<sup>1</sup>. Since the preparation of fractions D(F 1) and E(F 1) from B(F 1) was not given previously it will be described here.

## VASODEPRESSOR EFFECT OF SOYBEAN PHOSPHATIDE GIVEN IV

Fig 1—Response of blood pressure to repeated intravenous injections of 1.0 ml of a 6 per cent emulsion of soybean phosphatide fraction B(F-2) cat No 8 (1.6 kg). Time between injections 1 and 2 was sixteen minutes. Time between 2 and 3 was eighteen minutes.

*Preparation of D(F1) and E(F-1)* 20.5 Gm of fraction B(F1) were completely dissolved in 240 ml of dry chloroform and the solution was filtered. Three hundred sixty milliliters of 95 per cent ethanol were added slowly with shaking, and the light tan precipitate which formed was filtered off, dissolved in 100 ml of chloroform, and reprecipitated by the addition of 150 ml of 95 per cent alcohol. This material, fraction E(F1), was dried in vacuo and weighed 13.7 grams. The combined filtrates were concentrated to dryness in vacuo and yielded 6 Gm of fraction D(F1).

Each of the various fractions was blended, with dextrose present, and the vasodepressor activity was tested in the cat. Table III gives the results of these studies along with an evaluation of the emulsifying properties of the various fractions. The choline content of some of these fractions was determined by the method of Engel<sup>7</sup> and is included in the table since it serves as an index of the amount of lecithins present. Lipositol prepared according to the procedure of Woolley<sup>8</sup> was also included in these studies, and it was found to be no more active than the lipositol-low, alcohol-insoluble fractions.

The results obtained with all of the foregoing preparations indicated that the depressor substance was probably a degradation product of one of the phosphatides found in soybeans. Although the almost complete lack of solubility of the depressor substance in alcohol negated such compounds as free choline, ethanolamine, and many of their simple derivatives, some of these compounds were tested in the cat and the resulting effect upon blood pressure was compared with that of the unknown depressor. The character of the curve

## CHAPTER I FRACTIONATION OF SOYBEAN PHOSPHATIDE FRACTION B(F2) SCHMIDT 70

of the blood pressure response was not similar to that of the material in the soybean phosphatide fractions, and the extreme tachyphylaxis which resulted on repeated injection of phosphatides was also absent.

The following preparations also were made and tested for depressor activity

1 A dialysate of the fraction B(F 2) prepared by dialyzing a 6 per cent emulsion of this fraction against distilled water through a thin collodion membrane and concentrating the dialysate to the volume of the original emulsion. This material was inactive, whereas the residue was still completely active

2 Ten milliliters of Emulsion 35 placed in a 15 ml test tube and to which 0.5 Gm of sodium chloride was added. The tube was heated at 70°C for five minutes and then centrifuged while hot. The aqueous layer was tested for activity and was completely inactive

SIX SECOND INTERVALS

Fig. 2—Effect on blood pressure of route of administration of soybean phosphatide fraction 70 f cat No. 9 (2.3 kg)

- 1 0.1 ml 2.5 per cent 70 f intravenously
- 0 ml 2.5 per cent 70 f intraperitoneally
- 2 2.0 ml 2.5 per cent 70 f intraperitoneally
- 3 1.0 ml 2.5 per cent 70 f subcutaneously

Further fractionations of the preparation B(F 2) were carried out by means of solubilities in various solvents such as ethyl alcohol, acetone, chloroform, and mixtures of these solvents but none was effective in concentrating the depressor to a sufficient degree. Since the activity in the earlier fractionations followed those fractions high in inorganic constituents, separations were undertaken with acidic solvents. Acidic ethyl alcohol proved to be best for this purpose, and although many different fractionation schemes were carried out only one of the most successful is described in Chart I. This fractionation of B(F 2) yields a material referred to as 70 f which is a highly active depressor substance. The results of the tests for vasodepressor activity using fraction 70 f are given in Tables I and III. The marked susceptibility of the cat to the vasodepressor activity is well shown in the comparative data in Table I.

*Effect of Route of Administration (Other Than Intravenous) on Depressor Activity of Fraction 70 f*—To determine the effect of the route of administration on depressor activity, a 2.5 per cent emulsion of preparation 70 f was injected intraperitoneally into an anesthetized cat. Fig. 2 shows the results of a typical experiment, and it is apparent that instead of causing a decrease in blood pressure, a pressor response resulted. Oral administration of this preparation as well as intramuscular and subcutaneous administration was without effect. Hence the depressor effect of the phosphatide fraction is only evident when the material is given intravascularly.

*Effect of the Depressor Substance on Duodenal Muscle*—To determine whether or not the depressor material had an effect on smooth muscle contractions, a strip of rat duodenal muscle was connected to a lever in the usual manner and was immersed in oxygenated mammalian Ringer's solution. At intervals 0.4 ml of a 2.5 per cent emulsion of fraction 70-f was added, in each case the Ringer's solution was changed before the addition. Five per cent glucose solution was used as the control. The results of this experiment are

#### EFFECT OF DEPRESSOR MATERIAL ON SMOOTH MUSCLE CONTRACTION

Fig. 3—Contraction of rat duodenal muscle to successive stimulation with 0.4 ml of an emulsion of 2.5 per cent of soybean phosphatide fraction 70-f. Volume of Ringer solution was 200 milliliters;  $\frac{1}{2}$  was 5 per cent dextrose solution. Time lapses between 2 and 3, 3 and 4, and 5 and 6 were 5, 6, and 5 minutes respectively.

given in Fig. 3 and it is observed that the depressor material gives rise to a marked contraction of the muscle and that the contraction decreases with repeated addition of fraction 70-f.

#### DISCUSSION

The soybean phosphatide fraction B(F-2) described previously<sup>1</sup> for use as a stabilizer in fat emulsions for intravenous nutritional purposes has been found to possess a marked vasodepressor activity when injected into the cat. This activity was present in the commercial soybean phosphatide preparation from which this fraction was obtained. Since freshly prepared soybean phosphatides had little such activity, vasodepressor substance probably is formed sometime during or after the process of manufacture by oxidative or degradative changes. This view is supported by the fact that freshly prepared phosphatides became active depressants when allowed to stand at room temperature in contact with air.

The great species difference with respect to this vasodepressor activity was of interest. In the cat, 4 mg of fraction B(F-2) per kilogram of body weight caused a decrease in arterial blood pressure of 56 millimeters. Little or no

effect was obtained however, when 277, 39 and 86 mg quantities per kilogram of body weight were given to the rat, rabbit and dog, respectively. This difference is important in work concerning intravenous fat emulsions because the dog and rat are the animals usually used for testing such preparations. From clinical studies it appears that man is more sensitive to the vasodepressor than these three species but less so than the cat. It is obvious that it is desirable to test fat emulsions intended for clinical use in several species including the cat.

Several interesting characteristics of the pattern of the blood pressure response to the various phosphatide fractions have been observed. One of these was the step like manner in which the blood pressure returned to normal. This ranged all the way from a slight pause or dip to a drop back to the original low. In the latter case the return proceeded without any sign of another stepwise recant. Such a step phenomenon is not characteristic of the response to such compounds as acetylcholine, histamine, etc. Another difference between the soybean depressant and the other depressant materials tested was the relatively great tachyphylaxis that occurred following the initial response when an original drop of more than 10 to 20 mm had occurred. This tachyphylaxis made the exact quantitative evaluation of the potency of various preparations difficult but a fair comparison was still possible by allowing a suitable time lapse between injections and by using a standard injection of an emulsion of the fraction B(F 2) as an index of the tachyphylaxis.

The vasodepressor substance was not one of the known phosphatides or their simple degradation products such as free ethanolamine. It was nondialyzable through collodion and insoluble in water, alcohol and aqueous acid but soluble in acidified alcohol. The use of the latter solvent especially when hot may have resulted in various extraneous cleavages but no apparent increase in total original depressor potency occurred through its use. Perhaps the acid functioned by removing moisture ions from the depressor and thereby rendered it or its hydrochloride alcohol insoluble. Partial neutralization of the acidic solution caused the precipitation of the depressor along with salts. Ether extraction removed it from the latter and yielded a light yellow nitrogenous material.

The effect of the depressor material in causing a contraction of duodenal muscle suggests that the material could act directly on the blood vessel wall. It is of interest to note that a decreased stimulation of the muscle strip resulted on repeated application of the depressor. The sustained elevation in blood pressure which occurred when the phosphatide fraction 70 f was given intraperitoneally may have resulted because of stimulation of intestinal contraction.

Because of the vasodepressor effect of phosphatide fraction B(F 2) Emulsion 35<sup>1</sup> is not considered suitable for clinical use though it is adequate for experimental studies in the dog, rat or rabbit. Although phosphatide fractions low in depressor activity could be prepared these were either poor emulsifying agents or if they were suitable as an emulsifying agent they underwent changes on autoclaving that gave rise to toxic effects. Fraction C(F 1) (Table III) is a good example of a phosphatide fraction with no depressor activity, good emulsifying properties but one which is unsatisfactory following autoclaving. In general it appears that the more a phosphatide preparation is purified

the less stable it becomes to autoclaving. Fraction B(F-2) still remains the most suitable of the soybean phosphatide fractions for stabilizing fat emulsions for intravenous use. Only approximately half of fraction B(F-2) possesses good emulsifying properties, but the remainder of the preparation appears to provide stability to the fraction during autoclaving.

The question arises as to whether fraction B(F-2) can be used in a concentration of less than 3 per cent (as it is used in Emulsion 35) and stabilize an emulsion, yet not be present in such an amount that a depressor effect will be obtained. Emulsions containing 15 per cent fat, identical in composition to Emulsion 35 except that fraction B(F-2) has been reduced from 3 per cent to 0.5 per cent, have been prepared, and they do not affect the blood pressure of the cat. However, stability on standing and when added to plasma is not as great as desired. Further studies utilizing a costabilizer in addition to 0.5 per cent of fraction B(F-2) are reported in the following paper.

#### SUMMARY

1 A soybean phosphatide preparation, B(F-2), prepared for use as a stabilizer for fat emulsions for intravenous nutrition has been found to possess vasodepressor activity in man and the cat, little such activity in the dog, and none in the rat or rabbit.

2 The depressor material is not present in phosphatide fractions freshly prepared but develops, on standing, on contact with air. It does not appear to be acetylcholine, choline, ethanolamine, or any simple derivatives of these compounds. The depressor material has been concentrated considerably.

3 Fractions of phosphatide low in depressor activity have been prepared, but are either undesirable emulsifying agents or are adversely affected by autoclaving.

## PARENTERAL NUTRITION

### IX FAT EMULSIONS FOR INTRAVENOUS NUTRITION IN MAN

GEORGE V. MANN, M.D., ROBERT P. GEYER, PH.D.,  
DONALD M. WATKIN, M.D., AND FREDRICK J. STARE, M.D.  
BOSTON, MASS.

IN THE preceding paper<sup>1</sup> it was shown that the soybean phosphatide fraction known as B(F 2) which was used to stabilize emulsions caused a vasodepressor response in certain species particularly man and the cat, when used at a concentration of 3 per cent of the total emulsion. Although various depressor free fractions could be prepared from soybean phosphatides, they were either poor emulsifying agents or were adversely affected by autoclaving. Phosphatide fraction B(F 2)<sup>2</sup> remains the most useful stabilizing agent used in this laboratory for fat emulsions intended for intravenous nutrition, but if it is so used it must be present in concentrations less than 1 per cent if the emulsions are ultimately intended for clinical use in man. The purpose of this paper is to report observations on fat emulsions stabilized with 0.5 to 1 per cent of B(F 2) with and without the use of a costabilizer, and preliminary studies on the use in man of one of these fat emulsions given intravenously.

#### EXPERIMENTAL

All emulsions were prepared under nitrogen by the high pressure homogenization technique previously described using a pressure of 3500 to 4000 psi and a temperature of 85 to 92°C for five to ten minutes. Sterilization was accomplished by autoclaving the preparations in tightly capped nitrogen filled bottles for fifteen minutes at 15 psi. The size of the fat particles was ascertained by microscopic examination, and no emulsion was considered satisfactory from the viewpoint of particle size unless almost all of the particles were below 1  $\mu$  in size and no particles were observed larger than 4 microns.

The stabilizers used were soybean phosphatide fraction B(F 2) and Demal 14\* either singly or in combination. Coconut or corn oil in a final concentration of 15 per cent was used throughout. The composition and evaluation of these emulsions are given in Table I and it is seen that Emulsions 40 and 41 possessed the most desirable properties, i.e., very small particle size and no depressor effect in the cat or any other adverse physiologic effect following injection. Emulsions 40 and 41 contained 0.5 per cent phosphatide fraction B(F 2) as stabilizer and 1 per cent Demal 14 as costabilizer. Emulsion 40 was made with corn oil and Emulsion 41 with coconut oil. Since these two emulsions appeared to be most promising, only the experiments concerned with them will be reported.

*Animal Studies*—Six albino male rats weighing approximately 150 grams were injected daily with Emulsion 40 at a level of 2.0 ml per 100 grams body weight. Injections were made through a tail vein while the animal was under

\* All emulsions contained coconut oil 15 per cent, dextrose 4.3 per cent and water to make 100 ml with the exception of Emulsion 10 in which corn oil at 15 per cent was used as the source of fat.

† Response following single injections. Amounts in parentheses are maximum volumes used per kilogram of body weight.

light ether anesthesia. Twelve to fourteen daily injections were given and one week after the last injection the animals were autopsied. No gross changes were in evidence and histologic sections revealed no abnormalities. During the course of the injections a decrease in hemoglobin from an average of 14.5 Gm per 100 ml to 12.0 Gm per 100 ml occurred but a return to the normal values resulted during the postinjection period. Weight gain during the injection period averaged 2.4 Gm per day.

A similar experiment was performed with weanling rats and the results obtained substantiated those of the previous study.

Three adult female dogs weighing approximately 9 kilograms each were fed *ad libitum* a diet which consisted of 78 per cent Games Dog Meal, 2 per cent liver powder (Wilson 120), 10 per cent brewers' yeast, and 10 per cent crude casein. All dogs were weighed and infused daily and hemoglobin, hematocrit, cell counts and liver function tests were done at weekly intervals.

Infusions were begun with Emulsion 40 containing 15 per cent corn oil. This emulsion was well tolerated by the animals in amounts of 3 Gm of fat per kilogram body weight per day even at infusion rates up to 10 ml per minute, and no vomiting resulted even during the initial infusions. After an average of ten days however a distinct anemia was observed. In two of the dogs, Emulsion 40 was replaced with Emulsion 41 identical in composition except that 15 per cent coconut oil was the source of fat. Emulsion 41 was also well tolerated, and quite unexpectedly the anemia of these two dogs (Dogs 1 and 2) disappeared almost completely although infusions were continued for many days. The data for each dog are given in Table II and may be summarized as follows:

Dog 1 received daily infusions of fat for a period of eleven weeks. During the first five weeks the preparation was a corn oil emulsion (Emulsion 40) given in a dosage of 3 Gm of fat per kilogram per day and at rates varying from 5 to 10 ml per minute. The hemoglobin decreased from 15.4 Gm to 12.3 Gm per 100 ml and the hematocrit from 43.6 per cent to 30.5 per cent. At this time the animal's hemoglobin level was purposely reduced to slightly below 9 Gm/100 ml by bleeding. A marked reticulocytosis followed which demonstrated that the anemia produced by hemorrhage stimulated a reticulocyte response even though the animal had received daily infusions of fat for more than a month. At this time the coconut oil emulsion (Emulsion 41) was substituted and used during the last six weeks of the infusion period. It was given in increasing doses of 3, 4, 5, and 6 Gm per kilogram per day as indicated in Table II. There was a definite and rapid rise in hemoglobin, hematocrit and erythrocyte values during the last five weeks of infusion with the coconut oil emulsion despite the fact that the coconut oil was finally given at twice the level that the corn oil emulsion had been infused. Food consumption decreased as the quantity of fat infused was increased. The animal was sacrificed two weeks after the last fat infusion, autopsy disclosed no gross abnormalities and microscopic examination of tissue sections showed no abnormalities.

Dog 2 received twelve daily infusions of the corn oil emulsion (Emulsion 40) in the amount of 6 Gm of fat per kilogram of body weight per day and at a rate of 4 to 8 ml per minute. By this time a definite drop in hemoglobin and hematocrit had appeared. The fat infusions were stopped for four weeks by which time the blood picture had improved. Daily infusions with the coconut oil emulsion (Emulsion 41) were then started at the same rate and amount as had been used previously for the corn oil emulsion. While the hemoglobin and hematocrit again decreased during the next two weeks of infusion they began

to return to normal during the third and last week of infusion. Dog 2 was sacrificed two weeks after the last infusion and post mortem examination revealed no significant gross or microscopic changes from the normal.

Dog 3 received twelve daily infusions of the corn oil emulsion (Emulsion 40) at a level of 5 Gm of fat per kilogram of body weight per day and at rates varying from 5 to 10 ml per minute. These infusions were given, as it happened, during the last days of pregnancy. On the twelfth day, shortly after the infusion had been given, six healthy puppies were born. Fat infusions were continued for another twelve days but at an increased level of 45 Gm per kilogram body weight, and despite the extra load imposed by nursing, the hemoglobin and hematocrit values returned rapidly toward normal. The data are given in Table II. Four weeks later this dog was in excellent health. No autopsy was performed.

A supplementary study was done with rats to determine whether a difference between coconut and corn oil could be shown in this species with respect to the development of anemia. Two groups of ten rats each were injected daily for twenty-one days. One group received the corn oil Emulsion 40 and the other the coconut oil Emulsion 41. Hemoglobin determinations were done at three- to four-day intervals. Both groups developed a moderate anemia and no significant difference between the two emulsions was obtained.

*Clinical Trials With Emulsion 11*—As a result of the preceding animal studies, it was concluded that either Emulsion 40 or 41 in which the stabilizing agents were 0.5 per cent B(F-2) and 1 per cent Demal-14 were adequate for a careful clinical trial. They could be sterilized by autoclaving, were of small particle size, stable in contact with blood, did not affect blood pressure, and, except for a moderate and transient anemia, produced no physiologic or pathologic abnormalities after repeated daily infusions for periods of several weeks. The initial clinical trials were made with the intention of determining the immediate reactions of the patients and their tolerance to the rate of administration. Balance studies to test utilization and the contribution of infused fat to energy requirements were not attempted in these preliminary, short-term studies. The first three patients selected represented clinical problems of a hopeless nature, but which might at the same time derive some benefit from the supplementary calories provided.

*Patient 1* This patient was a 75 year old woman who entered the hospital in coma. A history was obtained of cardiovascular disease of several years' duration with symptoms of decompensation and signs of auricular fibrillation of three months' duration. Examination revealed a right hemiplegia. The patient remained semicomatose and unable to swallow. Tube feedings used initially were discontinued because of vomiting and the danger of aspiration. Although the patient could be kept hydrated with clysis, caloric insufficiency produced a weight loss of 33 pounds in the first six weeks of hospitalization and the patient became emaciated. On the forty-second hospital day, the patient was given 300 ml of Emulsion 41 (460 calories) in a period of 110 minutes. The infusion was made through a No. 20 needle. The equipment was arranged so that either the fat emulsion or a solution of 5 per cent glucose in water could be infused by gravity through separate Murphy drip bulbs by adjustment of the valve of a three way stopcock attached to the needle. Control determinations of temperature, pulse, respiration, and blood pressure were obtained at three ten minute intervals while glucose was being infused, then the stopcock was turned so as to substitute the emulsion. When infusing conscious patients, this arrangement allowed arbitrary choice of solutions without the patient's knowledge in order to better evaluate subjective symptoms.

# RESPONSE OF PATIENT 1 DURING INFUSION OF 300 ML OF FAT EMULSION (NO 41) INTRAVENOUSLY

Fig 1

# RESPONSE OF PATIENT 2 DURING 8 SUCCESSIVE DAYS OF INTRAVENOUS INFUSIONS WITH 300 ML OF FAT EMULSION (NO 41) DAILY

Fig

Fig 1 illustrates the response of Patient 1 to this infusion and it is seen that no abnormal reaction was observed. There was no further change in the clinical status of this patient. She was transferred to a nursing home two days later.

*Patient 2* This patient was a 78 year old woman admitted in a semicomatose state with a history of two years of mild "strokes" and a gradual loss of consciousness twenty four hours prior to admission. Physical examination showed an obese, plethoric woman, with enlarged heart and liver, pitting, ankle edema, and a right hemiplegia. The clinical diagnosis was multiple cerebrovascular thrombosis and generalized arteriosclerosis. The patient lost weight rapidly on a regimen of parenteral glucose, protein hydrolysate, and saline.

On the ninth hospital day the patient was recovering from a mild infection and had a temperature of 100° F. On this day 300 ml of Emulsion 41 were given without reaction. This amount was given on each of the succeeding seven days, amounting to 2,400 ml in all. Fig 2 illustrates the response of Patient 2 to these infusions, and it is seen that there was no abnormal reaction. During this period there was some improvement clinically of the patient's sensorium.

Since previous animal studies had indicated that continuous infusions of emulsions led to a mild anemia, this patient was followed with hematologic studies. During the eight days of infusion the patient's hemoglobin fell from 15.3 Gm to 12.0 Gm per cent. The hematocrit fell from 51 per cent to 42 per cent. This reduction of hemoglobin and hematocrit was undoubtedly due in part to the fat infusions.

Eleven days after the last infusion this patient expired and an autopsy was performed. At this time the patient was described as poorly nourished. The spleen, liver, and lungs were described as grossly normal. Histologically, the lungs revealed occasional small areas of atelectasis with a few infiltrating lymphocytes. The liver cells showed a fine cytoplasmic vacuolization similar to the changes of starvation and protein depletion. No granulomatosis or giant cell containing lesions were seen reminiscent of the lesions previously described in animals after infusions of some of our earlier emulsions<sup>3, 4</sup>.

A fat tolerance curve done after the seventh infusion in this patient by the turbidimetric method previously described<sup>5</sup> indicated the same prompt fall in concentration of the visible fat particles in the plasma as previously reported for rats and dogs.

*Patient 3* This patient was a 24 year old man in the terminal stage of glomerular nephritis. There was a five year history of proteinuria. Nine months previously edema had appeared, and for the prior two months the blood urea nitrogen and blood pressure had been very high, with several convulsions before entry. The patient was treated periodically in the hospital with an artificial kidney and maintained on a low protein intake. It was felt that a source of nonprotein calories in high concentration might lessen the renal burden. On the sixth hospital day, this patient was given 600 ml of fat Emulsion 41 (920 calories) in 120 minutes without reaction. The emulsion used was a new batch which had been assayed for sterility, pyrogenicity, and infusion reactions in rats, dogs, and cats and found to be satisfactory in all respects. The patient was alert and cooperative on this day, having been treated the previous day with the artificial kidney. He experienced no subjective reactions and could not distinguish whether he was being infused with 5 per cent glucose or the fat emulsion. On the following day another 600 ml of Emulsion 41 were given at a maximum rate of 5 ml per minute without reaction. General clinical improvement was readily apparent, though how much of this was due to the treatment with the artificial kidney two days previously and how much due to the fat emulsion could not be ascertained. On the next day the patient was given a third infusion of 600 ml of Emulsion 41 and at the end of the infusion complained of chilliness. Two hours later the oral temperature had risen to 102° F. Since the patient had been on the artificial kidney that day and since four previous bottles of the same batch of emulsion had not produced pyrogenic reactions in this patient, the fat emulsion was not considered the cause of the temperature rise. The response of this patient during the three days of fat infusion is given in Fig 3.

This patient's clinical condition rapidly grew worse in the ensuing days and on the thirteenth hospital day he expired after a uremic convulsion. An autopsy was performed.

RESPONSE OF PATIENT 3 DURING 3 SUCCESSIVE DAYS  
OF INTRAVENOUS INFUSIONS WITH 600 ML OF FAT EMULSION (NQ 41) DAILY

Fig 3

The visceral organs were essentially normal grossly and there was no histologic evidence of lesions attributable to the infused fat emulsion.

**Patient 4** This patient was an alert and intelligent 37 year old civil engineer who entered the hospital with a complaint of swelling of the ankles. There was a five year history of renal disease with a left monoplegia of one year's duration. The blood pressure was  $\frac{230}{150}$  with an enlarged heart and liver and extensive retinitis. This patient was placed on a low protein diet and treated with parenteral low salt albumin. With his complete and effective cooperation a trial of intravenous fat emulsion was made.

On the twelfth hospital day 600 ml of Emulsion 41 were given at a rate of 5 ml per minute without reaction. The patient stated that he experienced no unusual symptoms at the site of injection or elsewhere. There was no unusual taste sensation experienced although he stated that for two or three hours after the infusion he experienced a sensation of languor and epigastric fullness much like the satiation following a large meal. There was no nausea.

The following day another 600 ml of fat emulsion were given at a rate of 5 ml per minute. At the end of the infusion the patient had a sudden, mild shaking chill and in the next three hours the temperature rose to 100.8°F. The blood pressure was not changed. Emulsion from the infusion set was cultured and found to be sterile. The following day a third infusion of 600 ml of emulsion was given again. The last 300 ml were given at a rate of 12 ml per minute. There was no reaction subjectively or of the temperature or blood pressure. Hematologic studies on this patient revealed a fall of the hematocrit from 35 to 33 per cent and of the hemoglobin from 12.2 Gm to 11.5 Gm over the period of fat infusion. This patient was discharged with his clinical condition essentially unchanged.

**Patient 5** This patient was a 40 year old housewife with a complaint of shortness of breath and swelling of the ankles. There was a five year history of chronic pyelonephritis.

RESPONSE OF PATIENT 5 DURING INFUSION OF  
300 ML OF FAT EMULSION (NO 41) INTRAVENOUSLY

Fig 1

with mild hypertension and retinitis. On a low protein, low salt diet, she had done well although there was evidence of increasing izotemia.

The patient was given 300 ml of fat emulsion by the usual method with an infusion rate of 5 ml per minute. At the close of the infusion she experienced a shivering chill. The temperature rose to 102° F one hour later and gradually subsided (Fig 1). The remainder of the solution from the infusion bottle was cultured and found to be sterile. No further infusions were given this patient. The following day the patient developed a generalized papular eruption with pruritus. She complained of tender areas in the neck, and slightly enlarged, tender glands were palpable. The patient had been receiving a barbiturate *prn* during her hospitalization. Barbiturate medications were stopped. After several days the glands subsided and the rash disappeared with a dry, flaking desquamation. It was not established whether this cutaneous and glandular reaction was related to either the fat emulsion infusion or to barbiturate medication. The patient was discharged with her clinical condition unchanged.

**Patient 6** This patient was a 42 year old housewife who entered the hospital with complaints of diarrhea and loss of weight. The diarrhea had grown progressively more severe during the past thirteen years. Except for occasional remissions—the last following therapy with folic acid—the disease had been refractory to all methods of therapy. At this time the patient was 50 per cent below her ideal weight. Her principal symptoms were weakness and tetanic cramps consequent to low serum levels of calcium. Nitrogen and fat balance studies indicated a great deficit in absorptive capacity although a definite reduction of pancreatic enzymes could not be confirmed. In the absence of a successful therapy for the fundamental disease, this patient represented an example of an urgent need for adequate parenteral nutrition, particularly calories. However, because of difficult veins, a considerable psychosomatic problem, and the fact that “pyrogenic difficulties” were shortly to plague the fat emulsions, it was not possible to give sufficient parenteral emulsion to make a real contribution to the patient’s nutritional status. The subjective response to infusions of this patient was also difficult to interpret. The first infusion of Emulsion 41 to this patient was small, only 50 ml, but was given without any unfavorable reaction. After an interval

of one day a second infusion of the same emulsion in an amount of 150 ml was given with out reaction (see Table III, Patient 6 on 6/12 and 6/14). The following day a third infusion of the same emulsion in the amount of 150 ml was given and a mild pyrogenic reaction was obtained. On the next day the same batch of Emulsion 41 again was given to this patient in an amount of 300 ml and a pyrogenic reaction occurred with the temperature going to 102° F two hours after the infusion was finished.

TABLE III. CLINICAL STUDIES WITH FAT EMULSION 41

DATES 1948	AGE OF EMULSION (DAYS)	STUDIES	REACTION
4/30	0	Emulsion 41 Batch 9D 41—I prepared	0

		{ Sterility tests negative	0
		{ Pyrogen tests positive	Pyrogenic

Of all the patients, Patient 6 was the most sensitive to rate of infusion. Rates above 5 ml per minute led to nausea and on one occasion vomiting. At slower rates the subjective reaction was one of saturation and drowsiness.

Because of two consecutive pyrogenic reactions in Patient 6 no further infusions of fat emulsion were given to her at this time. However six weeks later additional infusions of Emulsion 41 were given again to Patient 6 but with no better results. In all Patient 6 was given 1500 ml of fat emulsion. Two months after the last infusion the patient expired and a post mortem examination was carried out. At death the patient was extremely cachectic. Examination revealed a granulomatous nonobstructing lesion of the bowel wall 45 cm below the pylorus. The etiology of this lesion is unexplained. Grossly and microscopically there was no evidence of the previous infusions of fat emulsion.

## DISCUSSION

When phosphatide fraction B(F-2) is used at a concentration of 0.5 to 1.0 per cent as the sole stabilizer of a 15 per cent fat emulsion, a good emulsion is obtained which will withstand autoclaving. This concentration of B(F-2) also produces minimal vasodepressor activity in the cat. It is felt, however, that such a low concentration of stabilizer may not be completely safe to protect the emulsion from breaking when it comes in contact with the electrolytes of the plasma. Hence a costabilizer of polyglycerol esters (Demal-14) has been used at a concentration of 1 per cent along with 0.5 per cent B(F-2) in a 15 per cent fat emulsion (Emulsions 40 and 41). A variety of studies with animals, using cats, rats, and dogs, indicated that except for a moderate temporary anemia Emulsions 40 and 41 appeared suitable for careful clinical trial.

Results on the first four patients were promising in that the emulsion was well tolerated with no changes in temperature, pulse, blood pressure, or respirations. Indeed, Patient 2 received 300 ml of Emulsion 41 (460 calories) per day for eight days in succession, and Patient 3 received an initial infusion of 600 ml of Emulsion 41 (920 calories) with no reaction and with definite clinical improvement.

The first batch of Emulsion 41 made up for clinical use was rather small, and when the preliminary trials with animals and sterility and pyrogen tests were completed, there remained seven 300 ml bottles of emulsion. These were completely used up in the first two patients, with no reaction (Batch SD-413, Table III). The second batch of Emulsion 41 (Batch SD-420) was made up in larger quantity and was used for the last two infusions of Patient 2 with no reaction. Likewise, this second batch of Emulsion 41 was given ten days later to Patients 3 and 6, and twelve days later to Patients 3, 4, and 6, all without reaction. However, on the following day (Table III, infusions on 6/15) pyrogenic reactions were obtained in two out of the three patients receiving this batch of fat emulsion. Since these were the first pyrogenic reactions observed, and since Patient 3 infused at the same time did not have a reaction, the significance of the pyrogenic reactions was questioned. Furthermore, emulsion from the infusion sets of all three patients was cultured and found to be sterile. Again on the following day two out of three patients had pyrogenic reactions, and two days later Patient 5 had a pyrogenic reaction (Table III, infusions on 6/16 and 6/18). Hence it appeared that something had developed in this batch of emulsion that caused a pyrogenic reaction. Three days following the last pyrogenic reaction in a patient, this batch of emulsion was found to be sterile but strongly pyrogenic in rabbits.

Thus it seems definite that the second batch of Emulsion 41 (SD-420) especially prepared for clinical use developed pyrogens of a nonbacterial nature twenty-six days after it was prepared, however, the first batch of Emulsion 41 (SD-413) remained pyrogen free for thirty-two days by which time the supply was exhausted (Table III). Additional studies have substantiated these results, namely, that while emulsions of the type of Emulsion 41, using B(F-2) at 0.5 per cent and Demal-14 at 1 per cent as stabilizers, can be used

satisfactorily in patients, the emulsions do undergo some type of change which gives rise to pyrogens. The exact cause or nature of this change is not understood at present. It does not seem to be due to contamination. It is accelerated by repeatedly autoclaving the emulsion.

In a discussion of the clinical use of fat emulsions it is desirable to caution against the possible instability of fat emulsions to electrolytes *in vitro*. Some of the emulsions prepared in this laboratory during the last few years have been found to be unstable when mixed with saline *in vitro*, however no instability was encountered with most of these emulsions when they were in contact with blood either *in vivo* or *in vitro*. Hence infusions of fat emulsions in man should not be given with an apparatus (flask, tubing or needle) through which saline has previously been given or vice versa unless the stability of the emulsion to saline has been established. That is why in the studies reported in this paper 5 per cent glucose in water (not saline) was the fluid used just prior to giving the fat emulsions.

#### SUMMARY

1 Fat emulsions for intravenous administration containing 15 per cent fat have been adequately stabilized with a combination of a soybean phosphatide preparation and a polyglycerol ester (Demul 14) at concentrations of 0.5 and 1 per cent respectively.

2 Such emulsions made with corn oil or coconut oil were well tolerated when given intravenously to rats, dogs and cats. Except for a moderate normocytic anemia which disappears shortly after the fat infusions are stopped, these fat emulsions gave rise to no apparent physiologic or pathologic difficulties, even after daily administration in generous amounts for periods of several weeks.

3 Such an emulsion containing 15 per cent coconut oil has been given to man in amounts up to 600 ml per day (940 calories) without unfavorable reactions. One patient received 300 ml of the emulsion daily for eight successive days without any unfavorable reaction. Post mortem examinations were later obtained on three of the six patients who received this emulsion and in no case was there any gross or microscopic evidence of pathologic changes related to the fat infusions.

4 Fat emulsions of the type used in these studies have been found to undergo some type of change over a period approximating four weeks that results in the formation of pyrogens and hence are not considered completely satisfactory for clinical use. The exact nature of this slow development of pyrogens is not known at present but it appears to be of nonbacterial origin.

The authors wish to express appreciation to Miss June Chipman, Mr. LeRoy W. Matthews, Mr. Harvey Quigley, and Mr. George Bradford for technical assistance and to the following companies who have supplied us generously with various materials used in this research: The Upjohn Company, Kalamazoo, Mich.; Merck and Company Inc., Rahway, N. J.; Gaines Division of General Foods Corporation, Hoboken, N. J.; Wilson Laboratories, Chicago, Ill.; Sheffield Farms Co. Inc., New York, N. Y.; Corn Industries Research Foundation, New York, N. Y.; and Anheuser-Busch Co., St. Louis, Mo.

## LABORATORY METHODS

### THE DETERMINATION OF TRUE GLUCOSE IN BLOOD BY REDUCTION OF FERRICYANIDE

THE PRODUCTION OF A LINEAR REPRODUCIBLE COLOR WITHOUT THE USE OF A  
STABILIZING AGENT IN MACRO AND MICROTECHNIQUES SUITABLE FOR  
VISUAL AND PHOTOELECTRIC COLORIMETRY

GEORGE R KINGSLEY M S,\* AND JOHN G REINHOLD, PH D  
PHILADELPHIA PA

A SYSTEMATIC study of several blood glucose methods<sup>1</sup> employing colorimetric or photometric measurement of the reduction of alkaline ferricyanide indicated that further improvement and simplification of such methods was possible. A sensitive method yielding a color of sufficient stability and reproducibility for measurement in a photoelectric colorimeter without the need for frequent recourse to standard solutions and giving precise results over a wide range of true blood sugar values is described in this paper. The method has the additional advantage of being applicable directly to protein free filtrates of low dilution (1:10 macromethod) as well as high dilution (1:100 micromethod).

#### MACROMETHOD

*Reagents*—(Chemicals used are of analytical reagent quality unless otherwise noted.)

*Alkaline Potassium Ferricyanide* Weigh exactly 184 Gm of anhydrous sodium carbonate and 98 Gm of potassium ferricyanide and dissolve together in 1 liter of distilled water. Keep in dark bottle away from light.

*Ferric Iron* Dissolve exactly 20 Gm of ferric ammonium sulfate ( $\text{Fe}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$ ) in 945 ml water and add 55 ml of 8% per cent orthophosphoric acid.

*Acid Cadmium Sulfate* 130 Gm cadmium sulfate ( $3\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$ ) or 10.99 Gm of anhydrous cadmium sulfate and 635 ml of exactly 1N sulfuric acid are brought to a volume of 1 liter with distilled water.

*1.1N Sodium Hydroxide*

*Stock Glucose Standard* 1.000 Gm made up to exactly 100 ml with 0.2% per cent benzoic acid.

*Standardization*—0.5, 1.0, 1.5, 2.0, 2.5, 3.0 and 4.0 ml of stock glucose standard are each diluted to 100 milliliters. 0.5 ml of these standards is treated in the same manner as 0.5 ml of the blood filtrate as outlined under Procedure for the micromethod. Readings may be plotted against concentration of glucose of the standards or a conversion factor (K) calculated:  $\text{milligrams glucose}/100 \text{ ml} = K(2 - \log \%T)^{-1}$ . Readings  $D(-\log T)$  of blanks were found to vary from 0.01 to 0.03 with Coleman spectrophotometers and with scale readings of Klett Summerson instruments from 0 to 8. If blanks much higher than these are obtained the reagents are contaminated and should be discarded.

*Procedure*—To 8 ml of acid cadmium sulfate solution add 1 ml of whole blood mix thoroughly, let stand one minute then add 1 ml of 1.1N sodium hydroxide and mix by shaking. Let stand fifteen minutes then filter through Whatman No. 40 filter paper or

preferably centrifuge at 1000 r.p.m. for five to ten minutes. To a test tube graduated 20 ml. add 0.5 ml. of the filtrate, then add 5 ml. of the alkaline potassium ferricyanide solution. Mix by twirling and place in boiling water bath for ten minutes. Cool two minutes in a water bath at 40° C. Add 5 ml. of ferric iron solution and mix by twirling. Allow to stand five minutes in the 40° bath. Dilute to the 20 ml. mark with distilled water. Mix and read in the photoelectric colorimeter within twenty minutes. A green filter transmitting light between 500 and 570 mμ with maximum transmission at 540 mμ is used.

A more dilute filtrate may be prepared by adding 1 ml. of whole blood to 15 ml. of a acid cadmium sulfate solution prepared as follows: 5.77 Gm. cadmium sulfate ( $\text{CdSO}_4 \cdot 8\text{H}_2\text{O}$ ) or 4.7 Gm. anhydrous cadmium sulfate ( $\text{CdSO}_4$ ) and 28.2 ml. of exactly 1N sulfuric acid are brought to a volume of 1 liter with distilled water. One minute after the addition and mixing of the blood, 1 ml. of 11N sodium hydroxide is added and the procedure continued as directed.

1  $K = 3.5$  for Coleman spectrophotometers, Models 6 & 14, using No. 6304B cuvette.

#### MICROMETHOD

##### Reagents—

*0.1 per cent Stock Glucose Standard*—Dissolve 100 mg. glucose and dilute to 100 ml. with 0.25 per cent benzoic acid.

*0.01 per cent Dilute Stock Glucose Standard*—Dilute 10 cc. of stock standard to 100 ml. with 0.25 per cent benzoic acid.

*Alkaline Potassium Ferricyanide*—Same as micromethod.

*Ferric Iron*—Same as micromethod.

*Dilute Acid Cadmium Sulfate for 0.05 ml. Pipette*—Dilute 40 ml. of reagent used in micromethod to 100 milliliters.

*Dilute Acid Cadmium Sulfate for 0.02 ml. Pipette*—Dilute 20 ml. of reagent used in micromethod to 100 milliliters.

*0.055N Sodium Hydroxide for 0.05 ml. Pipette*

*0.022N Sodium Hydroxide for 0.02 ml. Pipette*

*Standardization*—Measure 2, 4, 6, 8, 10, 12, 15, and 20 ml. of dilute stock glucose standard with a burette and dilute to 100 ml. with 0.25 per cent benzoic acid. Add 0.5 or 1 ml. of these dilutions to colorimeter tubes and treat in the same manner as directed for 0.5 or 1 ml. of the blood filtrate in the microprocedures. One milliliter of 1 to 100 dilution or 0.01 per cent stock glucose standard is equivalent to 10 mg. of blood glucose if the micromethod for 0.02 ml. of blood is used, or 8 mg. if the micromethod for 0.05 ml. of blood is used. Readings may be plotted against concentration of glucose of the standards or a conversion factor ( $K$ ) calculated: milligrams glucose/100 ml. =  $K(2 \log\%T)$ .

*Procedure for 0.02 ml. Pipette*—Add 0.02 ml. of whole blood to 1 ml. of dilute acid cadmium sulfate solution for 0.02 ml. pipettes in a small Kilm tube and mix by washing out pipette. Let stand for one minute. Add 1 ml. of 0.022N sodium hydroxide, stopper and mix.

1  $K = 503$  in the micromethod for 0.02 ml. of blood for Coleman spectrophotometers, Models 6 & 14, using No. 6304B cuvettes.

Let stand fifteen minutes, then centrifuge. Add 1 ml. of the clear supernatant filtrate to 15 ml. of alkaline potassium ferricyanide in a colorimeter tube graduated at 6 milliliters. Digest ten minutes in a boiling water bath. Cool two minutes in a 40° C. water bath. Add 15 ml. of the ferric iron solution, mix and allow to stand five minutes at 40°. Dilute to the 6 ml. mark and read in the colorimeter within twenty minutes. Make reagent blank by treating 1 ml. of distilled water in the same manner as 1 ml. of filtrate and set at 100 per cent transmission with light at 740 mμ wave length.

*Procedure for 0.05 ml. Pipettes*—Add 0.05 ml. of whole blood to 1 ml. of the dilute acid cadmium sulfate solution for 0.05 ml. pipettes in a small centrifuge tube and mix by washing out pipette. Let stand for one minute. Add 1 ml. of 0.055N sodium hydroxide, mix and stopper. Let stand fifteen minutes then centrifuge. Add 0.5 ml. of the supernatant filtrate to 1.25 ml. of alkaline potassium ferricyanide in a 5 ml. graduated Klett colorimeter tube. Digest ten minutes in a boiling water bath. Cool two minutes in a 40° C. water bath.

Add 1.25 ml of the ferric iron solution mix and allow to stand five minutes at 40° C. Dilute to the 5 ml mark and read in colorimeter within twenty minutes as directed in preceding meromethod.

#### EXPERIMENTAL

1 *Determination of Optimum Concentration of Reagents and Physical Conditions for the Production of a Stable Reproducible Linear Color*—Optimum concentrations of reagents were determined by studying the effects of variation in their composition and proportion on color development in several ferric cyanide reduction sugar methods. Tungstic acid filtrates of blood were employed. Whatman No. 40 filter paper free of reducing substances was used. Substitute reagents also were studied with the hope of discovering more desirable ones. It was found that a marked reduction in the concentration of sodium carbonate and phosphoric acid as compared with previous methods greatly increased the speed of the development and improved the stability of color. Lithium carbonate was found to exhibit the same characteristics as sodium carbonate when used in equivalent concentrations. Phosphoric acid in excess of the optimal concentration diminished the stability of color in the older ferric cyanide methods. A potentiometric study by Woods<sup>8</sup> of the oxidation of glucose by ferric cyanide has shown that increase of acidity retards the reaction. The concentration of other reagents was also reduced from that recommended by Folm and Malmros.<sup>1</sup> Cyanide carbonate reagent recommended by Horvath and Knehl,<sup>2</sup> has been shown by Sutter<sup>7</sup> and others to increase progressively for forty five minutes the ferrocyanide formation when heated. Small variations in the amount of sodium cyanide added also cause variations in the development of color. High values for blanks are common when cyanide is used and the range of the method is reduced. For these reasons sodium cyanide was omitted from the alkaline ferric cyanide reagent. In agreement with Klendshoj and Hubbard<sup>4</sup> and Horvath and Knehl<sup>2</sup> ferric ammonium sulfate was found to develop a more stable color over a greater range of concentration than other ferric compounds tested. These included ferric sulfate phosphate trihydrate and citrate. A 0.2 per cent ferric ammonium sulfate ( $\text{Fe}(\text{NH}_4)(\text{SO}_4)_2 \cdot 12 \text{H}_2\text{O}$ ) solution was found to give a linear relationship between color and glucose concentration up to 400 mg per 100 ml of glucose at any time after color was developed at room temperatures. The color gradually increased by about 5 per cent in twenty five minutes, then remained stable for more than one hour. The disadvantage of increasing color intensity after dilution to volume was overcome by warming five minutes at 40° after addition of the ferric ammonium sulfate to the reaction mixture. When so treated the solution could be read in the colorimeter immediately after diluting to volume and mixing. Only occasional samples showed an increase of 1 to 2 mg per 100 ml after standing twenty minutes. Ferric ammonium sulfate concentrations exceeding the 0.2 per cent recommended cause slow fading of color while less caused intensity of color to increase on standing.

All previous methods depending upon the formation of Prussian blue have used a stabilizing agent. When higher concentrations of reagents were used sodium lauryl sulfonate (Duponol) was found to stabilize the colloidal pigment

which otherwise precipitated when higher levels of glucose were examined. However, different samples of Duponol "p c" or "c" gave somewhat different blanks and caused a variation in time for full color development. When the concentration of reagents was reduced to that recommended in this paper it was found that the addition of Duponol to the ferric ion reagent did not increase the stability of the color developed, but prolonged the time required for its development and also increased the color of the blank. For these reasons the use of a stabilizing agent was abandoned.

Tungstic acid filtrates examined by the modified method gave results about 10 per cent higher than the Folin and Malmros<sup>1</sup> (2 to 33 mg per 100 ml) and Benedict<sup>9</sup> (0 to 40 mg per 100 ml) methods. A series of fifteen samples were used to compare the variability of the proposed ferricyanide method and the Folin and Malmros<sup>1</sup> method by three repeated determinations on preserved tungstic acid filtrates. Single determinations by the new method deviated from the mean by an average of 3.3 mg per 100 ml ranging from 0 to 7 mg on samples with blood sugars of 55 to 150 mg per 100 milliliters. On the same filtrates, the Folin and Malmros method showed an average deviation from the mean of 12.6 mg per 100 ml ranging from 4 to 21. The color developed by the Folin and Malmros<sup>1</sup> and the Benedict<sup>9</sup> methods was less stable and therefore less satisfactory for photoelectric determination than that developed by the methods herein described.

No special tubes are required for the new ferricyanide method, and as a minimal amount of sodium carbonate is used, gas bubble formation is avoided. No differences have been found after the reagents have been aged for about two months in contrast to the Folin and Malmros<sup>1</sup> and Benedict<sup>9</sup> reagents which undergo changes in sensitivity on standing.

*2 Determination of Optimum Concentration of Reagents and Physical Conditions for the Preparation of Protein-Free Filtrates for the Determination of "True" Glucose*—Although consistent results were obtained with tungstic acid filtrates, it was felt that the method would be more useful if true sugar values could be obtained. Protein-free centrifugates and filtrates prepared by various methods were studied with the modified ferricyanide method. Protein-free filtrates prepared from serum by copper-tungstate precipitation gave results comparable to tungstate filtrates. The copper-tungstate reagent could not be used on whole blood because stability of color was not obtained. Zinc or barium hydroxide could not be used for the same reason. However, acid cadmium sulfate and sodium hydroxide could be adapted to the ferricyanide method by modification of the original procedure of Fujita and Iwatake.<sup>6</sup>

A comparison of tungstic acid and cadmium hydroxide filtrates was made, and the nonfermentable substances (Table I) of the filtrates were determined. 0.5 ml of a 50 per cent suspension of yeast cells, washed free of reducing substances, was added to 5 ml of the cadmium filtrates in a centrifuge tube and incubated at 38° for thirty minutes and then centrifuged. The unfermentable reducing substance was found by this method to average 3 mg per 100 ml in cadmium hydroxide-treated specimens as compared with 25 mg per 100 ml expressed as glucose in tungstate-treated specimens.

TABLE I COMPARISON OF TOTAL REDUCING SUBSTANCES IN CADMIUM HYDROXIDE AND TUNGSTIC ACID FILTRATES AND NONFERMENTABLE REDUCING SUBSTANCES IN CADMIUM HYDROXIDE FILTRATES AS DETERMINED BY THE NEW FERRICYANIDE METHOD

NO	TUNGSTIC ACID FILTRATES	CADMIUM HYDROXIDE FILTRATES	
	TOTAL REDUCING SUBSTANCES (MG %)	TOTAL REDUCING SUBSTANCES (MG %)	NONFERMENTABLE REDUCING SUBSTANCES (MG %)
1	78	51	3
2	82	50	2
3	115	83	4
4	122	93	3
5	86	60	3
6	90	52	3

The effects of cadmium were evaluated by adding graduated amounts of glucose to a series of different cadmium hydroxide prepared protein free filtrates. Recoveries indicated that the amount of cadmium sulfate recommended did not interfere even if added in 5 to 10 per cent excess unless the protein content of the sample is very low (less than 4 per cent serum proteins or 2 million red blood cells), when excess cadmium may cause turbidity to occur during color development. In conditions of this kind turbidity may be avoided by reducing the protein precipitants twenty five per cent. Standard solutions of glucose added to whole blood (with correction for glucose present in the blood) gave readings identical with those of glucose standards in water. Further tests of a possible interfering action of cadmium were made on filtrates obtained by combining acid cadmium sulfate and sodium hydroxide in the proportions used for protein precipitation the addition of blood being omitted. If 0.5 ml of 1 to 6 or 1 to 8 dilutions of such filtrates was added to glucose standards no effect on final color development was observed. Cadmium hydroxide filtrates of blood may be kept several days at 5° C without measurable loss of sugar.

TABLE II RECOVERIES OF GLUCOSE ADDED TO 1 ML OF OXALATED WHOLE BLOOD\* WITH ACID CADMIUM SULFATE REAGENT†

NO	GLUCOSE IN 100 ML OF BLOOD (MG)	GLUCOSE ADDED (MG)	GLUCOSE RECOVERED (MG)	PER CENT RECOVERED

\*Fasting

†Calculated from cell volume

Fasting venous blood glucose was determined on the plasma and whole blood of thirteen hospital patients by the new ferricyanide method and the Folin and Malmros method using cadmium hydroxide filtrates (Table III). Glucose from the cells was calculated by means of hematocrit determinations. The glucose values by the Folin and Malmros method averaged 4 mg per cent lower in plasma and 4 mg per cent higher in cells, differences that are probably not significant. It is believed, as previously stated, that the large individual differences result from the lower precision of the Folin and Malmros method which has not shown good agreement between repeated determinations. Values for nonfermentable reducing substances obtained by the two methods on cadmium filtrates were the same. It was shown by experiment that the Folin and Malmros method was unaffected by amounts of cadmium equivalent to that in the protein-free filtrates.

The new ferricyanide method with cadmium hydroxide filtrates and the Folin-Wu method<sup>10</sup> with acid tungstate filtrates were compared, using venous blood from twenty-three normal fasting male subjects (Table IV). Glucose ranged from 73 to 85 mg per 100 ml of venous blood as determined by the new ferricyanide method, which is slightly lower, but agrees favorably, with the range of 77 to 90 obtained by Somogyi<sup>11</sup> on the venous blood of ninety-three fasting normal individuals. A range of 85 to 110 mg of glucose per 100 ml of venous blood was obtained by the Folin-Wu method. The latter method was used for comparative purposes as it is probably the most widely used of all sugar methods in clinical laboratories.

## SUMMARY

A method for the photocolormetric determination of 'true sugar' in whole blood is described. The conditions necessary for obtaining a stable, linear, reproducible color for the quantitative determination of glucose by its reduction of ferricyanide in alkaline solution are outlined.

A normal fasting glucose concentration of 73 to 85 mg per 100 ml of venous blood was obtained.

# SIMPLE TEST FOR THE APPROXIMATE ESTIMATION OF BLOOD CREATININE AND GLUCOSE IN ONE PROCEDURE

EMANUEL E MANDEL, M D,\* AND EDWARD B LEHMANN, M D †  
CHICAGO, ILL

WITH THE TECHNICAL ASSISTANCE OF ROBERT DORIN, M S, AND  
LORRAIN SCHMELZLE, B S ‡

THE use of picric acid as a protein precipitating agent in the determination of creatinine in the blood was recommended previously by one of the authors (E E M) in collaboration with others<sup>1,3</sup> During a recent re-evaluation of the bedside modification of that method<sup>4</sup> it was found that the brief heating of the blood-picric acid mixture as prescribed at times resulted in a filtrate which yielded a much more intense color reaction than warranted by the true creatinine content, as determined with the routine precision method. This phenomenon was attributed to the glucose present in the blood, in accordance with reports long since published<sup>5,8</sup> Hence, it was not only obvious that the original technique of quick creatinine estimation<sup>4</sup> needed revision, but it also appeared that the same method might lend itself to a simultaneous determination of the blood sugar. This notion was verified by subsequent experiments, the results of which are outlined below.

## REAGENTS

- (a) Saturated picric acid
- (b) 10 per cent sodium hydroxide

## APPARATUS

- (A) Standardized test tubes approximately 5 inches long and  $\frac{1}{2}$  inch in diameter, graduated at 1, 4, 5, and 10 milliliters
- (B) Small funnel fitted with folded filter paper (Whatman No 1)
- (C) Medicine droppers
- (D) Boiling water bath (cup or beaker)
- (E) Potassium bichromate standards ranging from 0.15 to 3 per cent solutions (Table I) contained in test tubes identical with those described under A, but not graduated, and sealed with paraffin. They are prepared from a 10 per cent solution, acidified with 1 drop of concentrated sulfuric acid per 100 ml, by progressive dilution with distilled water, and are stable for years if kept in a cool and dark place.
- (F) Three slot comparator with ground glass background to be viewed against daylight or an artificial daylight bulb.

## PROCEDURE

*Creatinine Estimation*—Fill a graduated test tube (A) with reagent (a) to the 4 ml mark. Add venous blood with a syringe or a medicine dropper up to the 5 ml mark, using either a freshly drawn or a preserved specimen rendered noncoagulable. Shake thoroughly and let stand for five minutes or until the reddish brown color of the mixture changes to greenish brown. Filter into a similar test tube until the clear yellow filtrate reaches the 1 ml mark. Adjustments of volume can be made readily with a medicine dropper. Add 1 drop of reagent (b), shake, and allow fifteen minutes for development of yellow orange color.

Received for publication Feb 9 1949

Read in comparator against bichromate standards for creatinine estimation (Table I). In the absence of such standards, comparison with a specimen known to contain a normal concentration of creatinine, or with a simple mixture of 1 ml of reagent (a) with 1 drop of reagent (b), may be utilized. An intensity of color in excess of that of either improvised standard denotes an abnormal creatinine level. An increase of 3 mg per cent or more can be detected readily without the aid of a comparator.

TABLE I CORRELATION OF GLUCOSE AND CREATININE LEVELS WITH CONCENTRATION OF POTASSIUM BICHROMATE STANDARDS

BLOOD CREATININE (MG PER 100 ML)	POTASSIUM BICHROMATE (MG PER 100 ML)	BLOOD GLUCOSE (AT AVERAGE CREATININE LEVEL OF 1 MG %) (MG PER 100 ML)
0.8	150	50
1.0	200	67
1.6	250	78
2.0	300	90
2.3	350	95
2.6	400	100
3.2	500	112
3.7	600	120
4.2	700	130
4.6	800	138
5.0	900	145
5.4	1 000	150
5.7	1,100	155
6.0	1 200	160
6.4	1 300	165
6.8	1 400	170
7.1	1 500	175
7.5	1,700	180
8.0	1 900	185
8.4	2 000	190
9.1	2 200	195
9.8	2 400	200
10.2	2,500	205
14.0	3 000	215

*Glucose Estimation*—Having served for the visual creatinine determination the same specimen is immersed in a boiling water bath for about three minutes. A change in color to a more or less intense reddish brown occurs depending upon the concentration of glucose present. Periods of two to ten minutes used for boiling the specimen produce the same results both visual and spectrophotometric. The glucose level can be estimated roughly immediately after removal of the tube from the water bath by one who has gained some experience with the test.

For better accuracy add distilled water to the 5 ml mark and after mixing, compare the resulting color with bichromate standards as listed in Table I. With color reactions more intense than that of the 2 400 mg per cent bichromate solution (above 200 mg per cent of glucose), dilute the specimen with another 5 ml of water by making up to the 10 ml mark\*. Without this additional dilution of samples with higher glucose contents the deepness of their color renders visual comparison unreliable and does not permit accurate spectrophotometric correlation with potassium bichromate standards (see below). Doubling of the value obtained for the diluted specimen from Table I yields the true blood glucose level. Further dilution (replacing 5 ml of the 10 ml specimen with water) and quadrupling of the result is necessary for blood samples with a sugar content greater than 400 mg per cent.

With these higher dilutions, the influence of an elevated creatinine on the glucose reaction is negligible. They were not employed with lower glucose concentrations because

If the capacity of the test tubes (A) used is less than 10 ml, transfer 1 ml. of the specimen to another tube (A) and make up with distilled water to the 5 ml mark prepared for this purpose. Fourfold dilution if necessary is implemented by adding water up to the 4 ml mark.

# A QUANTITATIVE SPINAL FLUID GLUCOSE MICROMETHOD FOR THE PEDIATRIC WARD LABORATORY

LYTT I GARDNER,\* M D, HELEN BERNAN, B S, ELSIE A MACLACHLAN, B S,  
AND MARY L TERRY, A B  
BOSTON, MASS

IT HAS been well established that a lowered glucose concentration in spinal fluid is an important clue in the early diagnosis of meningitis,<sup>1,4</sup> particularly when other spinal fluid findings are lacking. Since this diagnosis frequently must be established at night when laboratory facilities are limited or unavailable, reliance is often put on the qualitative reaction of Benedict's solution.<sup>5</sup> This reaction is difficult to evaluate quantitatively and requires 0.75 ml to 1.0 ml of spinal fluid, an amount unavailable from some infants.

To provide a rapid quantitative estimation of spinal fluid glucose the following adaptation of Lewis and Benedict's picric acid method for glucose<sup>6,7</sup> has been employed. A single 0.25 ml sample of spinal fluid suffices for the determination. No colorimeter is required. Results are expressed as milligrams per cent glucose and usually do not vary from results obtained with the Folin ferricyanide method<sup>8</sup> by more than 5 mg per cent.

## METHOD

*Reagents*—Sodium picrate 10 per cent aqueous solution. This is prepared free of the red colored picramic acid as described by Folin.<sup>10†</sup>

Sodium carbonate 10 per cent aqueous solution. This and the sodium picrate solution are stored in gravity flow stock bottles with dropper tips on the tubing.

Standard glucose solution 200 mg per cent. Ten additional dilutions from 10 to 100 mg per cent are made from this stock solution.

*Apparatus*—Permanent color standards. These are easily made from 10 by 75 mm soft glass test tubes. Tubes for permanent standards and for the reaction should be of the same inside diameter. This may be measured with a caliper or by delivering water into several tubes from a 10 ml pipette. Those with the same water level are selected. The upper portion of the test tube is drawn out to a tip which is broken off. Permanent colored solutions are made by adding equal quantities of glucose standard and dilutions 10 per cent sodium carbonate solution, and 10 per cent sodium picrate solution to a test tube. This is placed in boiling water for eight minutes. The eleven colored solutions so prepared are introduced by dropper into the drawn out tips of the 10 by 75 mm test tubes which are sealed off in a flame. This makes eleven permanent standards between 10 and 200 mg per cent glucose which may be kept in a wooden comparator block.

Reaction tubes. 10 by 75 mm Pyrex test tubes are used.

Received for publication Feb. 9, 1949.

\*Research Fellow in Pediatrics, Harvard Medical School.

†Transfer 500 Gm moist picric acid to a Florence flask of 1.5 liters capacity. Add 60 ml of acetone. Shake with a little warming under hot tap water until all the crystals are dissolved. Dissolve 250 Gm of anhydrous sodium carbonate and 100 Gm of sodium chloride in 7.5 liters of warm water in a 4 liter beaker. While stirring with a large agateware spoon add the acetone solution gradually to the alkaline salt solution. When the reaction is finished let stand in cold water for about half an hour and then gradually pour the now nearly solid mass on a hardened filter on a large Buchner funnel (4 cm diameter). Wash the picrate with about 1 liter of 5 to 10 per cent sodium chloride solution. Dry at room temperature or over a radiator. Make to 10 per cent aqueous solution.

Fig 1—An easily made comparator block for the permanent color standards. Attached cross wise is a reaction tube with rings scored at 0.25 ml, 0.50 ml, and 0.75 milliliter.

*Procedure*—From a graduated 1 ml pipette add 0.25 ml spinal fluid to a reaction tube. Then add 0.25 ml 10 per cent sodium picrate solution and an equal quantity of 10 per cent sodium carbonate solution. An alternative procedure, which avoids the use of pipettes, is to calibrate the reaction tubes by scoring them with a diamond pencil at 0.25 ml, 0.50 ml, and 0.75 ml. The spinal fluid and solutions may then be added from clean medicine droppers. Shake. Place in boiling water eight minutes. Put in comparator block and compare with permanent standards. Express results as milligrams per cent glucose.

#### RESULTS

Table I presents a comparison of spinal fluids analyzed for glucose by Folin's ferricyanide method and by the picrate method. The data show that variation in spinal fluid total protein does not influence the similarity of results with the two methods.

Creatinine reacts with sodium picrate to produce a color similar to that produced by glucose. Table II shows a comparison of spinal fluids analyzed

TABLE I. COMPARISON OF ANALYSES OF SPINAL FLUID FOR GLUCOSE BY THE FOLIN FERRICYANIDE METHOD AND BY THE PICRATE METHOD

TOTAL PROTEIN (mg %)	GLUCOSE (mg %)	
	FERRICYANIDE METHOD	PICRATE METHOD
168	64.5	65
41	62.1	60
28	55.0	55
40	94.7	100
31	58.8	55
45	55.0	55
96	68.9	70

52	60.0	70
80	54.0	60
56	66.0	70
80	42.0	35

Average difference of picrate method values from ferricyanide method values =  $\pm 3.47$  mg per cent glucose

TABLE II. COMPARISON OF ANALYSES OF SPINAL FLUID FOR GLUCOSE BY THE PICTATE METHOD WITH AND WITHOUT CREATININE IN A CONCENTRATION OF 5 MG PER CENT

TOTAL PROTEIN (MG %)	FOLIN CUPRAIDE METHOD GLUCOSE (MG %)	PICTATE METHOD	
		GLUCOSE (MG %)	
		NO CREATININE	CREATININE ADDED
38	74.0	80	80
30	66.6	70	70
45	66.0	70	70
128	66.2	70	70
84	27.7	—	40

for glucose by the picrate method with 5 m. per cent creatinine added to one group. This concentration was found by Myers and Fine only in severe nephritis.<sup>11</sup> Comparison of the two groups shows similar results for glucose except in the spinal fluid containing least glucose where the picrate method gave a higher reading. Hence in the rare patient with both meningitis and severe nephritis this error might occur.

In the absence of meningitis spinal fluid sugar reflects hyper and hypoglycemia.<sup>1, 12</sup> The 200 mg per cent standard was included to detect hypoglycemia if it exists.

## SUMMARY

A modification of the Lewis and Benedict picric acid method for glucose is described for use with spinal fluid requiring only 0.25 ml of spinal fluid. No colorimeter is required.

Results agree closely with the Folin cupraide method for glucose (average difference  $\pm 3.47$  m. per cent). The condition in which spinal fluid creatinine may cause error is discussed.

The authors are indebted to Dr. Allan M. Butler for helpful suggestions.

## ACID PHOSPHATASE TEST FOR IDENTIFICATION OF SEMINAL STAINS

SIDNEY KAYE, M Sc  
RICHMOND, VA

A TEST for the identification of seminal stains as a means of determining the accuracy of charges of rape must have a high degree of reliability with almost no margin of error.

The isolation of spermatozoa properly fixed and stained is by far the most satisfactory test for the demonstration of male ejaculate. However, chemical identification for the presence of seminal fluid adds further proof. In some instances chemical identification may be of more importance since it is not always possible to demonstrate the presence of intact spermatozoa with both head and tail, or even to identify microscopically the separate parts with certainty. In old specimens especially, some of the tails may be missing or abnormally twisted and the disjointed sperm heads are extremely difficult to identify and may be confused with spores, pus cells, or artifacts. In such situations and in aspermia or azoospermia\* in which the ejaculate lacks spermatozoa, other reliable microchemical tests are desirable.

The first microchemical test for seminal stains, described by Florence in 1896, has been used generally and accepted by scientific laboratories and law enforcement agencies. The procedure is simple, using a modified Wagner's reagent (16 Gm potassium iodide, 25 Gm iodine, dissolved in 30 ml water). At the line of confluence between the drop of extract and reagent, dark rhombic crystals of choline iodide may be microscopically observed. Results with the Florence test are not conclusive and occasionally may be erroneous.<sup>6b</sup>

If soap is used in the extraction, the test may be negative, moisture and putrefaction are sources of error. Albumin, glycerophosphoric acid, choline, trimethylamine, and extracts of mushrooms, corn, blossoms of plants, onions, and many other materials may interfere or give false positive results. Many attempts have been made to modify the Florence test to increase its specificity but none of the modifications are reliable. The subject has been adequately reviewed by Pollak.<sup>6a</sup>

Its first demonstrated that dried seminal stains give a characteristic fluorescence under ultraviolet light. However, this same brilliant characteristic fluorescence also may be obtained by many other substances and is therefore nonspecific for semen. It is of some value in locating suspected stains over large areas of garments and then marking these for later extraction.

From the Office of the Chief Medical Examiner Commonwealth of Virginia and the Department of Legal Medicine Medical College of Virginia

Received for publication Jan 26 1949

\*Aspermia is the congenital or acquired obstruction of the ducts preventing passage of sperm from the sex glands. azoospermia is the condition of immature cells of spermatogenesis which may be temporary or permanent due to frequent intercourse alcoholism or internal disease.<sup>6a 6b</sup>

or tactile perception or from ultraviolet light observation that the stain is widely and thinly dispersed or diluted the size of the area to be extracted should be increased. Body fluids and the common stains will not interfere since it was found that even in concentrated form these do not have an increased acid phosphatase activity. (See Table I)

Since the usual common contaminants that may simulate the appearance of seminal stains all have a relatively low acid phosphatase activity (Table I) and stains produced by semen have such a high acid phosphatase activity there is still a wide margin for error allowed if the minimum value for interpretation of a positive test is set at 25 units per milliliter of solution.

In the past occasion has presented itself where the precipitin test of Farnum may have been performed to differentiate between stains of human or animal origin. It is believed that if the possibility of the stain being of monkey origin can be ruled out the positive acid phosphatase test would suffice to indicate a prostatic secretion of human origin.

#### SUMMARY

In the legal proof of rape scientific evidence must be specific and should allow no margin of error.

The microchemical tests including the Florence test heretofore used in the identification of seminal stains have been nonspecific.

A microchemical test suggested by Hansen and Rusfeldt is described based on the high acid phosphatase level of seminal fluid of human origin. This promises to be both a specific and sensitive procedure for the positive identification of seminal stains as an adjunct to the demonstration of whole spermatozoa and of particular value in cases of aspermia or azoospermia.

#### CONCLUSIONS

1 The acid phosphatase method of recognition of seminal stains is particularly good in that differences between positive and negative results are easily interpreted.

2 The reaction is very sensitive and appears to be specific for seminal fluid of man or monkey only. Alkaloids, common food stains and body fluid stains do not interfere with the test.

3 The test can be performed simultaneously with the demonstration of fixed and stained spermatozoa without loss of material tested.

4 Seminal stains give positive tests even after six months.

specimen with 3 ml of water, repeat the extraction and tease the sample with a small medicine dropper, using the same 3 ml of original water. Allow sufficient time for a complete extraction, then perform an acid phosphatase determination on 1 ml of the filtered extract. It is even better to centrifuge the extract, examine the residue, and stain for spermatozoa in an accepted manner (Giemsa or Gram stain is satisfactory), in addition to doing an acid phosphatase test on the supernatant fluid. These tests may be performed simultaneously with the same original extract.

The procedure used for these experiments is a modification of the King-Armstrong method described by the Paul Lewis Laboratories, however, any accepted procedure for the determination of acid phosphatase is satisfactory, but particular attention should be given to the comparative results and technique employed (incubation time, reagents, etc.). In positive cases where the samples examined were sufficient, in no instance were the high values doubtful as to interpretation, regardless of results or technique used. A control should be simultaneously run to rule out possible interference. Positive results are indicated by the marked, increased acid phosphatase activity in comparison with the low acid phosphatase activity of body and food contaminants as shown in Tables I and II.

TABLE II ACID PHOSPHATASE VALUES FOR SEMINAL FLUIDS

\*Of cloth stained with seminal fluid and dried

The color intensity obtained with seminal stains is too great to read directly. Consequently, dilution of the final color with distilled water is necessary in order to approximate the color intensities of standards calibrated for colorimetric readings. The dilution factor must be taken into consideration when making the final calculations.

It is not always practical or possible to extract a definite unit area as was previously suggested since absorbent properties cannot always be taken into consideration of the different cloths and stains on materials such as grass, soil, wood and rocks. Also, inasmuch as it is reasonable to assume that the area concentration of a stain will be unevenly distributed with its highest concentration toward the center of the dried stain, judgment should be used in determining the size of the sample. An area of approximately 1 sq cm usually will suffice.

#### INTERPRETATION

An acid phosphatase activity of 25 King-Armstrong units per milliliter of extract from an area of approximately 1 sq cm should be considered positive for seminal stains. This value was arbitrarily established by observation and comparison with stains of fruit, vegetables, body fluids, and with stains produced by semen. With seminal stains, conditions may be quite varied, depending upon size, unit concentration, thickness, complete extraction, dilution factors produced by rain, washing, or contaminants. These variables are difficult to control or estimate accurately. Therefore, good judgment is necessary in determining the size of the sample to be taken. If it is obvious from visual

or tactile perception or from ultraviolet light observation that the stain is widely and thinly dispersed or diluted the size of the area to be extracted should be increased. Body fluids and the common stains will not interfere since it was found that even in concentrated form these do not have an increased acid phosphatase activity. (See Table I.)

Since the usual common contaminants that may simulate the appearance of seminal stains all have a relatively low acid phosphatase activity (Table I) and stains produced by semen have such a high acid phosphatase activity there is still a wide margin for error allowed if the minimum value for interpretation of a positive test is set at 25 units per milliliter of solution.

In the past occasion has presented itself where the precipitin test of Farnum may have been performed to differentiate between stains of human or animal origin. It is believed that if the possibility of the stain being of monkey origin can be ruled out the positive acid phosphatase test would suffice to indicate a prostatic secretion of human origin.

#### SUMMARY

In the legal proof of rape scientific evidence must be specific and should allow no margin of error.

The microchemical tests including the Florence test heretofore used in the identification of seminal stains have been nonspecific.

A microchemical test suggested by Hansen and Rusfeldt is described based on the high acid phosphatase level of seminal fluid of human origin. This promises to be both a specific and sensitive procedure for the positive identification of seminal stains as an adjunct to the demonstration of whole spermatozoa and of particular value in cases of aspermia or azoospermia.

#### CONCLUSIONS

1 The acid phosphatase method of recognition of seminal stains is particularly good in that differences between positive and negative results are easily interpreted.

2 The reaction is very sensitive and appears to be specific for seminal fluid of man or monkey only. Alkaloids, common food stains and body fluid stains do not interfere with the test.

3 The test can be performed simultaneously with the demonstration of fixed and stained spermatozoa without loss of material tested.

4 Seminal stains give positive tests even after six months.

## CULTIVATION OF MYCOBACTERIUM TUBERCULOSIS

### A COMPARISON OF HYDROCHLORIC ACID AND TRISODIUM PHOSPHATE IN THE PREPARATION OF SPUTUM AND OF THE USE OF FLUID DUBOS DAVIS MEDIUM AND PETRAGNANI MEDIUM

MARGARET BEATTIE \*  
BERKELEY CALIF

IN 1946 Coipel and Stoner<sup>1</sup> described the use of trisodium phosphate in the preparation of sputum for the diagnostic culture of mammalian types of *Mycobacterium tuberculosis*. These workers reported that this organism was not destroyed by contact with a 10 per cent solution (23 per cent  $\text{Na}_3\text{PO}_4 \cdot 12\text{H}_2\text{O}$ ) of trisodium phosphate for a week at room temperature and that contaminating organisms in sputum were destroyed without hazard to the tubercle bacillus by contact for twenty four hours at 37° C. Van Vranken reported a comparison of the use of oxalic acid and trisodium phosphate in the treatment of sputum specimens for culture. She found that the use of trisodium phosphate yielded more positive cultures than the use of oxalic acid both when acid fast organisms were observed in direct smears and when direct smears were negative. Since such a procedure would be particularly useful in a teaching laboratory where time is limited as well as in a diagnostic laboratory where specimens are received at various times during the day it was decided to compare this new technique with that described by McNabb<sup>3</sup> which utilizes a 3 per cent solution of hydrochloric acid in the treatment of sputum for cultivation. McNabb's technique has been used for more than ten years in this laboratory.

The use of the liquid medium described by Dubos and Davis<sup>4</sup> has been studied by a number of workers both as a medium for detecting tubercle bacilli in pathologic material and as an assay medium in tests for antibiotic activity against the bacillus. Foley<sup>5</sup> who compared fluid Dubos medium and guinea pig inoculation in the cultivation of *Mycobacterium tuberculosis* from sputum, obtained growth in the fluid medium in fifty and growth in the guinea pig in fifty four of the fifty seven sputum specimens tested. Goldie<sup>6</sup> reported cultivation of *Mycobacterium tuberculosis* in fluid Dubos medium from 116 of 400 sputum specimens. No other medium was used and guinea pigs were not inoculated by this worker. In no instance did growth fail to occur in the culture when acid fast bacilli had been observed in smear preparations of the sputum. In cultures from thirty four sputum specimens, growth in the medium was observed when no acid fast bacilli had been seen in direct smear preparations of the specimens.

From the School of Public Health, University of California.  
Received for publication Jan. 14, 1949.  
\*Associate Professor.

Wolinsky and Steenkin<sup>8</sup> reported fluid Dubos medium as satisfactory for testing the effect of streptomycin on *Myco tuberculosis*. Wong, Hambly, and Anderson<sup>9</sup> found Dubos-Davis medium suitable for demonstrating the antibiotic activity of subtilin against the tubercle bacillus.

For this study sputum specimens were obtained from four sanatoria and the Laboratories of the California State Department of Public Health. The sputum was homogenized and equal portions were treated with acid (McNabb's technique<sup>3</sup>) and trisodium phosphate (Corper and Stoner's technique<sup>1</sup>). Each portion of treated sputum was planted on Petriagnani medium (modification of Saenz and Constil<sup>10</sup>), and more than half of the portions were inoculated into fluid Dubos-Davis medium.<sup>4</sup> No selection of specimens to be planted in the fluid medium was made.

*A Comparison of the Effect of Treatment of Sputum With Hydrochloric Acid and Trisodium Phosphate in Preparation for Culture*—Of 245 sputum specimens treated with hydrochloric acid and trisodium phosphate (Table I),

TABLE I. GROWTH OF ACID-FAST ORGANISMS ON PETRAGNANI MEDIUM FROM SPUTUM USING ACID-TREATED (MCNABB) AND PHOSPHATE-TREATED (CORPER AND STONER) PORTIONS

	NUMBER OF SPECIMENS
Growth, acid-treated portion	150
Growth, phosphate-treated portion	
No growth, acid-treated portion	66
No growth, phosphate-treated portion	
Growth, acid-treated portion	21
No growth, phosphate-treated portion	
No growth, acid-treated portion	8
Growth, phosphate-treated portion	
Total specimens	245

no growth of acid-fast bacilli on Petriagnani medium was observed from either portion of sixty-six specimens. Of the 179 specimens in which viable acid-fast bacilli were found, growth was observed on the medium inoculated with both portions of 150 sputum specimens. In twenty-one of the remaining specimens, growth of acid-fast bacilli which produced colonies typical of *Myco tuberculosis* occurred on medium inoculated with the acid-treated sputum portion, but no growth of such organisms was observed on the medium inoculated with the corresponding phosphate-treated portion. From eight specimens, growth of *Myco tuberculosis* was obtained from the portion treated with phosphate but not from the corresponding portion treated with acid. It was noted in these latter cultures that the medium was overgrown with contaminants which made the detection of rare colonies of *Myco tuberculosis* impossible.

Growth appeared earlier on the medium inoculated with acid-treated portions of the sputum specimens in 79 of the 150 specimens where growth was obtained from both portions (Table II). Since the cultures were observed only at weekly intervals, no fine differences could be seen. From sixty-five specimens, colonies were observed at the same time regardless of the method of treatment. From six specimens colonies were observed earlier on medium

inoculated with phosphate treated portions than on medium inoculated with acid treated portions. These acid treated specimens were all contaminated, which may account for the failure to discover colonies of *Mycobacterium tuberculosis*. Contaminants were completely suppressed in the cultures from the portions treated with phosphate.

TABLE II TIME OF APPEARANCE OF GROWTH FROM ACID TREATED AND PHOSPHATE TREATED SPUTUM SPECIMENS

ACID TREATED EARLIER	PHOSPHATE TREATED FASTER	SAME TIME	TOTAL
79	6	65	150

Record was made as to the relative amount of growth observed in cultures from the paired specimen portions (Table III). Only those cultures which had obviously greater amounts of growth (from two to one hundred times) were classified as greater. If the difference was less obvious the amount of growth was designated as equal. Of the 150 specimens containing viable tubercle bacilli in both portions, the amount of growth from 119 was greater in cultures from the acid treated than from the phosphate treated portion. From eighteen specimens the amount of growth was approximately the same. More growth

TABLE III AMOUNT OF GROWTH FROM ACID TREATED AND PHOSPHATE TREATED SPUTUM SPECIMENS

ACID-TREATED GREATER	PHOSPHATE TREATED GREATER	EQUAL AMOUNT	TOTAL
119	13	18	150

was noted in cultures from thirteen phosphate treated portions than in cultures from the corresponding acid treated portions. No contamination of cultures made from the phosphate treated portions was noted while in the corresponding cultures from the portion of sputum treated with acid there was considerable overgrowth by contaminants. Probably less growth of *Mycobacterium tuberculosis* was observed because of the presence of these contaminants in the cultures.

Stained preparations were made from the suspended sediment from each treated sputum portion as well as from the growth on culture medium. It was observed that acid fast bacilli in stained preparations from phosphate treated sediments or from cultures grown from phosphate treated portions in the first or second week were fragmented and distorted in morphologic appearance and irregular in staining reactions. The contrast in the appearance of organisms in stained preparations from acid treated sediments or cultures grown from acid treated portions was marked in that the organisms from the acid treated portions always appeared as nonfragmented, typical tubercle bacilli. The appearance of acid fast bacilli in stained preparations from well developed colonies after the third or fourth week of incubation did not differ when grown from acid or phosphate treated portions of sputum.

*Comparison of Growth in Dubos Davis Medium and Petragram Medium*—Most of the Dubos Davis medium used was supplied by Difco Labora-

tures for experimental purposes 12 grams of Bacto Tb Broth Base Experimental were added to 100 ml of 5 per cent glycerol solution This mixture was sterilized at 121° C for twenty minutes To the cooled medium 10 ml of Bacto Tb Medium Serum Experimental were added aseptically and the finished product was dispensed in screw-cap Pyrex test tubes Ninety-six of the 257 plants were made in Dubos-Davis medium prepared in this laboratory according to the formula described by Dubos and Davis<sup>4</sup> Yeast autolysate, crystalline bovine albumin, and Tween 80 were used

The difference in growth in the two fluid media used is not statistically significant The Difco Experimental medium was used for the first 161 specimens and the medium made in the laboratory of the School of Public Health was used for the last ninety-six specimens The apparent superiority of this latter medium is probably due to increased facility in the preparation of smears in the later period of the study

Of the 257 (Table IV) sputum specimen portions planted on Petriagnani medium and into Dubos-Davis fluid medium, growth was observed in both media in 156 portions No growth was observed in either medium in cultures from sixty-nine sputum portions The results were in disagreement in thirty-two

P Petriagnani medium

D Dubos Davis fluid medium

instances Twenty-two times growth was observed on Petriagnani medium and not in Dubos-Davis fluid medium, and ten times the reverse was true Because the specimens used in the study were largely from patients with tuberculosis, the rate of agreement was so high (225 of 257) that the results could not be subject to statistical evaluation The growth of acid-fast bacilli in either of the two media under consideration was not greater than might have occurred by chance in this series of specimens

One of the advantages claimed for Dubos-Davis fluid medium is rapidity of growth which facilitates the rendering of an earlier report than is possible when solid medium is used However, if smear preparations are made from the growth on Petriagnani medium, it is possible to observe pairs or clumps of acid-fast bacilli a week or ten days before colonies are visible, and frequently a report can be made as early as is possible when fluid medium is used The technical difficulties encountered both in the making of the fluid medium and of the stained preparations of growth in the medium are greater than in the making of medium or stained preparations from the growth on Petriagnani medium The amount of time gained by cultivation in fluid medium is not great enough to compensate for the technical difficulties encountered

The effect of treatment with hydrochloric acid or trisodium phosphate as reflected in growth in fluid (Dubos Davis medium) or on solid (Petragnani) medium was observed in 127 acid treated and 130 phosphate treated portions of sputum (Table V)

TABLE V GROWTH IN DUBOS DAVIS MEDIUM AND PETRAGNANI MEDIUM INOCULATED WITH ACID TREATED AND PHOSPHATE TREATED SPUTUM PORTIONS

MEDIUM	127 ACID TREATED PORTIONS				130 PHOSPHATE TREATED PORTIONS			
Petragnani	Growth	No growth	Growth	No growth	Growth	No growth	Growth	No growth
Dubos Davis	Growth	No growth	No growth	Growth	Growth	No growth	No growth	Growth
Number	8	33	10	2	74	36	12	8

Growth was obtained in both media from 82 of 127 acid treated and from 74 of 130 phosphate treated portions of sputum. Neither medium revealed growth of *Mycobacterium tuberculosis* after inoculation with thirty three acid treated and thirty six phosphate treated portions. Eight specimen portions treated with trisodium phosphate grew in Dubos Davis fluid medium and not on Petragnani solid medium, whereas only two acid treated portions which grew in Dubos Davis fluid medium failed to grow on Petragnani medium. It is apparent that the bacilli surviving in the phosphate treated sputum found conditions more favorable for growth in the fluid medium. The nature of the sample (majority specimens positive) and the small number of differences involved makes a statistical evaluation of the results impossible.

#### SUMMARY AND CONCLUSIONS

Two hundred and forty five sputum specimens were homogenized and equal portions treated with hydrochloric acid (McNabb's technique) and trisodium phosphate (Corpey and Stoner's technique). Each portion was cultured on Petragnani medium and the rate and amount of growth of acid fast bacilli producing colonies recognized as typical of *Mycobacterium tuberculosis* were observed. Of 179 specimens from which growth was obtained, 150 yielded cultures from portions treated by both methods. This high proportion of agreement is a function of the weight of the excessive number of specimens containing tubercle bacilli from patients under treatment in sanatoria. (Only 74 of 245 specimens failed to show acid fast bacilli in stained preparations of the sediments used as inocula.) Divergent results were obtained with twenty nine specimens (growth from acid treated and not from phosphate treated portions in twenty one instances, and the reverse in eight instances). This difference was tested and shown to be not significant, that is the difference does not indicate the superiority of either method for the treatment of sputum in preparation for culture. The distorted appearance of the organisms in smear preparations from the phosphate treated sediments and young cultures is evidence that this treatment adversely affects the organisms. While these numbers are too small to yield statistically valid evidence the combined observations suggest that the use of trisodium phosphate tends to reduce the number of viable organisms and

to affect adversely the surviving bacilli. A sample which included a larger number of sputum specimens containing few organisms would more adequately test the techniques. The experimental evidence presented suggests that the use of trisodium phosphate for the treatment of sputum in preparation for culture may adversely affect the growth of the bacilli.

Dubos-Davis fluid medium and Petriagnani solid medium were equally effective in the cultivation of *Myco tuberculosis* from the specimen material tested in this study. The sample was so weighted in favor of positiveness that no statistically valid differences could be demonstrated. Acid-fast bacilli in sputa treated with trisodium phosphate appear to grow less readily on Petriagnani medium than the same specimens treated with hydrochloric acid. Some of these trisodium phosphate treated specimens grew in fluid medium and not on solid medium, which suggests that the fluid medium may be more satisfactory under these conditions. Because of technical difficulties in the preparation of Dubos-Davis fluid medium and in the preparation of stained smears from the growth of acid-fast bacilli in this medium, it would seem that there is little advantage in the wide-scale adoption of this medium in public health laboratories.

The technical assistance of Seiko Akahoshi, Mary Craig, Margeurite Jackson, and Joan James (senior students) is gratefully acknowledged. The collection and dispatch of specimen material used in this study by the bacteriologists in the laboratories of the State Department of Public Health and the State Sanitaria is also appreciated. The generous supply of experimental medium provided by Difco Laboratories, Detroit, Mich., is gratefully acknowledged.

# BACTERIOPHAGE TYPING OF *SALMONELLA TYPHI*

A REPORT OF TYPING IN MICHIGAN, 1947-1948

N D HENDERSON MS AND W W FERGUSON PH D  
LANSING MICH

BACTERIOPHAGE typing of *Salmonella typhi*\* has had a fairly brief but spectacular career since the development of this procedure by Craigie and collaborators in 1938. Numerous workers in various parts of the world have given it trial and have attested to its value. Nevertheless considering its importance to the epidemiologist and to the clinician who is interested in furthering public health the phage typing method has had only limited use. A recent canvass of public health laboratories in this country reveals that approximately seventeen institutions are employing the phage typing procedure today.

The possibility of application of the V<sub>1</sub> phages in the treatment of typhoid fever has not been overlooked by investigators. Knouff and associates<sup>1</sup> have used type specific phages intravenously in the treatment of fifty six patients with typhoid fever. They report that within twenty four to forty eight hours after treatment was begun patients who had been comatose regained their appetite and became cheerful and alert. Desianleau<sup>2</sup> has made use of mixtures of the four V<sub>1</sub> phages of Craigie and Yen<sup>3</sup> for intravenous therapy.

The major use of V<sub>1</sub> phage will undoubtedly continue to be in conjunction with the detection and identification of typhoid carriers. If the clinician who attends a sporadic case of typhoid fever as well as the epidemiologist who investigates an outbreak were to request the typing of all new strains of *S. typhi* isolated from either cases or suspected carriers the beneficial results would soon be evident to both the physician and the public health authorities. Should a new carrier be discovered for even a part of the sporadic cases that occur the total elimination of the disease would be much hastened. For it is evident that the known carrier who is excluded from food handling occupations and who is aware of the possibility of infecting others is seldom a hazard.

The initial discovery that led to typing was the finding by Craigie and Brandon<sup>4</sup> of certain strains of bacteriophages which would lyse typhoid bacteria bearing the V<sub>1</sub> or so called virulence antigen. Four V<sub>1</sub> specific phages were isolated by Craigie and Yen<sup>5</sup> one of which had the peculiar ability to adapt itself to certain strain differences of cultures of *S. typhi* containing V<sub>1</sub> antigen. These strain differences were not demonstrable by any means other than V<sub>1</sub> phage action. By adaptation and selective propagation of variants of this unusual phage eleven type specific phages were produced. These phages when applied to numerous strains of typhoid bacteria isolated from a variety of cases and localities demonstrated that the types of *S. typhi* were limited in number and were readily differentiated.

From the Division of Laboratories Michigan Department of Health

Received for publication March 14 1949

The nomenclature used in this paper is that of the Kauffmann White schema

It was further observed that there was a notable agreement of the results obtained in the laboratory with epidemiologic data.<sup>6</sup> For example, the recovery of the same phage type from a carrier and a group of connected cases was found to agree with the results of field investigations. On the other hand, the recovery of dissimilar types from a carrier and a group of related cases was found sufficient grounds for excluding the carrier from consideration as the source of the outbreak. In the large majority of such cases further investigation revealed the carrier responsible for the outbreak.

Of first importance is the fact that phage types of *S. typhi* have, with only a few rare exceptions, been found to remain stable both in vivo and in vitro. Thus it is possible to determine the phage type of the typhoid organism which a carrier is excreting, with the expectation that the type will not change either in the original or in a new host.

New phage types of *S. typhi* have been recognized since the original work of Craigie and Yen and today there are twenty-five known types. The typing technique,<sup>3, 13</sup> however, is relatively unchanged from the method worked out in 1938.

#### OBSERVATIONS

Previous to 1948, the Michigan Department of Health investigated two outbreaks of typhoid fever in which bacteriophage typing contributed necessary evidence for indication of responsible carriers.\* Because of these experiences in which the value of typing was clearly shown, the technique was instituted in our laboratories as a trial procedure in October, 1947. Over a period of one year the method of Craigie and Yen<sup>3</sup> was applied to 432 cultures of *S. typhi* which were isolated from 209 individuals, representing both cases of typhoid fever and carriers.

Table I shows the various types identified during the period October, 1947, to October, 1948. Of the 432 cultures, we were able to type 341 (78.90 per cent),

†Isolations

\*The typing of strains from both outbreaks was carried out by courtesy of Dr. James Craigie.

while 91 (21.10 per cent) proved to be untypable. Our experience with untypable strains is evidently the same as that of many other workers. Buckle<sup>7</sup> in his comprehensive review of typing all over the world, reports that 21.96 per cent of typhoid strains were found by various people to be untypable.

During the period covered by this report there were 83 reported cases of typhoid fever in Michigan from which we received 208 cultures for typing. Positive typings were obtained on 167 (80.28 per cent). Cultures from typhoid carriers, for the same period totaled 224 of which 174 (77.70 per cent) were typed. Among the 50 untypable cultures isolated from carrier specimens were seven strains of a small colony variant of *S. typhi* which appeared to be similar to those described by Morris and co-workers.<sup>8,9</sup> The various small colony strains were all isolated from repeat specimens from the same carrier and proved to be W in form.

The distribution of types found in Michigan is comparable for the most part to that reported by authors in other parts of the world.<sup>7</sup> Phage type E<sub>1</sub> predominated in our series making up 33.60 per cent of the total cultures received. Included in the 145 type E<sub>1</sub> strains are cultures isolated from two outbreaks.

In September, 1947, cases of typhoid fever were reported from a limited area on the outskirts of one of Michigan's larger cities. Investigation showed that a factor common to all patients was the drinking water which came from a neighbor's well. Bacteriophage typing confirmed the fact that all cases were probably infected from a single source, since all cases yielded cultures which were phage type E<sub>1</sub>. It was discovered that the owner of the well had recently installed running water in his house and at the same time had provided a new bathroom and septic tank. The disposal field for the septic tank was located quite close to the well, and once the tank was in use cases of typhoid fever began to appear in the neighborhood.

Members of the family owning the well were not affected, probably because they had discontinued use of the well water. Within a comparatively short time there were fourteen cases of typhoid. Specimens from the four members of the family were examined and two were found positive for *S. typhi*. It was soon proved that Grandmother S. was a typhoid carrier excreting phage type E<sub>1</sub> organisms and that her granddaughter was a probable contact carrier. The granddaughter like her grandmother excreted phage type E<sub>1</sub> organisms.

The second type E<sub>1</sub> outbreak involved persons eating in a factory cafeteria. Epidemiologic evidence was again supported by phage typing. Specimens from seven patients contained cultures of *S. typhi* which were all phage type E<sub>1</sub>. Investigation of the food handlers revealed a typhoid carrier who was excreting phage type E<sub>1</sub>. The closing of the cafeteria resulted in the cessation of the outbreak.

Other than these two epidemics the remainder of the 208 case cultures were obtained from sporadic cases of typhoid fever. Bradley<sup>10</sup> refers to these sporadic cases as "chinks in the complex armor of modern sanitation" and states further that "it is only by counting these sporadic cases which fail to initiate outbreaks that we have a true measure of the efficiency of our systems."

It will be noted from Table I that 10 strains of phage type D<sub>4</sub>HP<sub>56</sub> were identified. Phage D<sub>4</sub>HP<sub>56</sub> is the newest of typing phages and was produced by Craigie<sup>11</sup> from cultures submitted by the Michigan Department of Health following an outbreak in Highland Park, Mich., in the summer of 1946. A detailed report of this outbreak is in preparation.<sup>12</sup> As far as we are aware, the isolation of D<sub>4</sub>HP<sub>56</sub> has not been reported elsewhere in the literature.

Our typing experiences have included numerous opportunities to examine repeat cultures from several individuals. We have typed successfully thirteen cultures isolated from each of two individuals, and in one case we have received fifteen cultures of the same type from one person. With but one exception, repeat specimens have all yielded the original type. The exception was a carrier who was apparently excreting two phage types. A discussion of this carrier will be presented in a forthcoming paper.<sup>12</sup>

At the beginning of this study it was our intention to conduct a survey of the 266 known carriers in Michigan for the purpose of indicating the phage type, where possible, to the Bureau of Disease Control. The desirability of having all known carriers typed has been stressed by numerous workers in this field, among whom are Craigie<sup>13</sup> and Morris and associates.<sup>14</sup> Our original intention has been only partially fulfilled, chiefly because cultures have been submitted from only 105 carriers. However, there is some doubt in our minds about the value of a complete typing on all carriers in Michigan, at least from the standpoint of epidemiologic control. It has been our experience that we have not received a culture from a case of typhoid fever who was infected by a carrier known to the Bureau of Disease Control. This fact was confirmed by the Director of the Bureau who stated that there have been only three cases of typhoid fever traceable to known carriers since the carrier control program was begun in 1932.<sup>15</sup>

Korns and Trussell<sup>16</sup> state that at the time of their writing 465 known chronic carriers were listed in New York State. It is estimated that 2,500 carriers are included in New York's population. It seems probable that a similar condition exists in Michigan. However, in the vast majority of cases, the carrier will be an unknown. In our limited experience the indications are that phage typing will be of value in this state, especially for incrimination of the true carrier in sporadic cases and outbreaks of typhoid fever.

#### SUMMARY

- 1 Bacteriophage typing has been applied to 432 cultures of *S. typhi* isolated in Michigan. Positive typings were obtained with 341 cultures representing thirteen different phage types. Among the 341 cultures were 167 from active cases of typhoid, while 174 cultures were typed from carriers. Eleven phage types were found among the case cultures and twelve were demonstrated from carrier cultures.

- 2 Ten strains of the new phage type D<sub>4</sub>HP<sub>56</sub> were identified.

- 3 Two epidemics, in which phage typing was of value in arriving at a solution, are discussed.

4 Attention is drawn to the fact that there have been only three cases of typhoid fever in Michigan that were traced to known typhoid carriers since 1932. It is felt that the known typhoid carrier is seldom a public health menace.

## FORMATION OF ANTIBODIES IN HUMAN SUBJECTS AFTER THE INGESTION OF HEAT-KILLED BRUCELLA ABORTUS

ABRAHAM I. BRAUDE, M.D., DAVID GOLD, B.S., AND DOROTHY ANDERSON, B.S.  
MINNEAPOLIS, MINN.

THE agglutination test is widely used in the diagnosis of brucellosis. Results must be interpreted cautiously, however, because agglutinins are known to appear in the sera of persons who do not have brucellosis. Those conditions other than active brucellosis in which serum agglutinins for *Brucella* may be present are shown in Table I. The maximum titers which have been observed are also listed. After therapy with streptomycin and sulfadiazine, there is a persistent elevation of titer for as long as a year following complete remission in some patients.<sup>1</sup> These individuals have been checked carefully at the University of Minnesota Hospitals for evidence of continued bacteremia as well as clinical signs of infection, and neither has been found. It is well known that the introduction of *Brucella* antigens into the tissues, either intradermally for diagnostic purposes or for therapeutic ends, stimulates the production of agglutinins.<sup>2</sup> Similar inoculation with cholera antigens has the same effect according to the work of Eisele, McCullough, and Beal.<sup>3</sup> Other conditions in which cross agglutinins for *Brucella* occur are tularemia and typhoid fever.<sup>4</sup> In addition, it has been suggested that the titer of *Brucella* agglutinins may rise in response to an anamnestic reaction stimulated by another infection. Boits<sup>5</sup> mentions a rise to 1:160 occurring in pneumococcal pneumonia.

These examples probably account for only a small percentage of what might be called "false-positive reactions." At the University of Minnesota Hospitals, Aagaard<sup>6</sup> has observed that *Brucella* agglutinins were present in 93 per cent of blood samples obtained from 352 consecutive rural patients who were being studied in a dispensary service for various causes. A diagnosis of brucellosis was established in only one of these patients. The present investigation was undertaken to determine whether the agglutinins demonstrated in the sera of these patients could have been produced by the repeated ingestion of pasteurized milk containing large numbers of nonviable *B. abortus*. Dolman, Hudson, and Mathias<sup>7</sup> studied the sera of healthy volunteers who drank suspensions containing about 210 billion *B. abortus* in divided doses over a period of six weeks. They found that no rise in serum agglutinins resulted and they concluded that it was unlikely that a titer of 1:20 or higher could be provoked in man by the ingestion of milk containing dead *Brucella* organisms. Only eight persons were included in their experiment.

From the Division of Internal Medicine, University of Minnesota Hospitals and Medical School.

This investigation was supported (in part) by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, United States Public Health Service.

Received for publication Feb. 23, 1949.

TABLE I. CONDITIONS OTHER THAN ACTIVE BRUCELLOSIS IN WHICH SERUM AGGLUTININS FOR *BRUCELLA* MAY BE PRESENT (TITER OF AGGLUTININS)

Following successful anti-brucella therapy	1 2,560
After injection of Brucella antigens for skin test or vaccine therapy	1 1,280
After cholera vaccination	1 2,560
Tularemia	Low
Typhoid fever	1 160
Anamnesic reactions	1 160

## METHODS

*Br abortus* strain 1257 obtained from the National Institute of Health, was used throughout this study. Cultures grown for forty eight hours on tryptose phosphate agar were suspended in physiologic saline solution and were killed by heating at 65° for thirty minutes. The suspensions prepared in this manner were carefully checked for sterility and phenol was added in a concentration of 0.5 per cent. Appropriate concentrations of bacteria were made by adjusting the density of the suspensions in a photoelectric colorimeter. The colorimeter had been standardized at a density of 1 million *Brucella* cells per milliliter by means of a suspension of living organisms whose colony count had been determined by the standard pour plate method. Guinea pigs were selected as the initial subjects because of the demonstration by Ratner and Gruelke that undigested antigens are absorbed through the normal gastrointestinal wall of these animals at all ages. Healthy guinea pigs which had been obtained from reliable sources and which weighed approximately 400 grams were used. Water was withheld from their diet during the experimental period as it was found that animals which were not thirsty failed to swallow the *Brucella* suspensions. The aqueous suspensions were fed to guinea pigs by inserting the tip of a tuberculin syringe into their mouths and slowly injecting a measured volume. The animals were divided into two groups as shown in Table II. One group received a single feeding of 100 billion organisms. The other group received the same amount in ten divided feedings over a period of fifteen days. Blood was drawn for agglutination tests by cardiac puncture immediately preceding the period of feeding and also three and five weeks after this period was started.

TABLE II. FAILURE TO INDUCE THE FORMATION OF AGGLUTININS IN GUINEA PIGS FED HEAT KILLED *BR ABORTUS*

NUMBER OF GUINEA PIGS	NUMBER OF ORGANISMS PER FEEDING	NUMBER OF FEEDINGS	NUMBER DEVELOPING AGGLUTININS
9	100 billion	1	0
8	10 billion	10	0
Total 17			0

The effect of ingestion of these organisms was also studied in human volunteers. A summary of the procedure which was used for feeding these persons is given in Table III. The first group was composed in part of medical students in apparent good health. The remainder were young men who had recovered from acute polyomyelitis and were hospitalized in a convalescent home. The general condition of these patients was excellent. The subjects in Groups 2 and 3 were hospital patients. The vast majority of these were hospitalized for

TABLE III. METHODS OF ADMINISTERING HEAT KILLED *BRUCELLA* TO THREE GROUPS OF HUMAN SUBJECTS

GROUP	NUMBER OF SUBJECTS	NUMBER OF ORGANISMS	VEHICLE	NUMBER OF FEEDINGS	LENGTH OF FEEDING PERIOD
1	27	100 billion	Water	1	
2	76	100 billion	Pasteurized milk	10-20	10-20 days
3	8	1 billion	Pasteurized milk	10-12	12-20 days

plastic surgery or treatment of fractures. Organic disease of the gastrointestinal tract was demonstrated in only four of the sixty-seven individuals. Those in Group 1 received a single feeding of 100 billion *Brucella* in water. Preliminary studies were made with this large dose to determine whether there was any possibility of producing agglutinins by the ingestion of *Brucella*.

In the case of Groups 2 and 3, an attempt was made to reproduce the naturally occurring circumstances in which heat-killed *Brucella* may be ingested in pasteurized milk. This was done by the addition of the *Brucella* suspension once a day to milk which the patients consumed in their regular hospital diet. This milk was furnished to the University Hospital by the University of Minnesota School of Dairy Husbandry where it is pasteurized and bottled. Samples were tested for whey agglutinins on several occasions and the titers obtained were found to range from 0 to 1:10. By far the greatest proportion of this pooled milk came from *Brucella*-free herds. The small percentage of milk coming from animals infected with brucellosis was so greatly diluted that the final pasteurized product which was ingested by the hospital patients can be considered free of all but negligible amounts of *Brucella* antigen or antibody.

Members of Group 2 received 100 million organisms daily in this fashion for ten to twenty feedings during periods of ten to thirty days. The dose was reduced to a million organisms daily in Group 3 to determine whether a relatively small number of cells might be effective. Blood was collected when the feedings were commenced and two to three weeks thereafter. Agglutination tests were performed on each sample of blood by the standard tube method.\* *Brucella* opsonocytophagic tests were performed on sixteen subjects by the method of Jersild.<sup>9</sup> These were interpreted on the basis of the Foshay nomogram.<sup>10</sup>

#### RESULTS

Agglutinins failed to appear in the sera of any of the seventeen guinea pigs (Table II). Agglutinin production occurred in human subjects, however, in each of the three categories (Table IV). Of the twenty-three subjects who were fed a massive number of heat-killed *Brucella*, four developed agglutinins. This indicated the feasibility of experimenting with smaller numbers, and it was found that after the repeated ingestion of 100 million cells, significant titers of agglutinins were detected in eleven of the thirty-six persons. When the total number was reduced to 1 million daily, one of eight additional patients showed a rise in titer. Of the entire total of sixty-seven individuals, agglutinins were produced in sixteen or 23.5 per cent.

In Tables V, VI, and VII there is an analysis of the individual agglutinin responses. Surprisingly high titers developed in group 1. One individual in this group displayed a rise in titer from 0 to 1:640, two to 1:160, and one from 1:20 to 1:80. The last-mentioned change was significant because there was not only a four-fold rise in titer but also a striking change in the phagocytic index.

TABLE IV. AGGLUTININ FORMATION FOLLOWING THE INGESTION BY HUMAN SUBJECTS OF HEAT-KILLED *BR.* ABORTUS

GROUP	NUMBER OF SUBJECTS	NUMBER OF ORGANISMS PER FEEDING	NUMBER OF FEEDINGS	NUMBER DEVELOPING AGGLUTININS
1	23	100 billion	1	4 (17.0%)
2	36	100 million	10-20	11 (30.5%)
3	8	1 million	10-12	1 (12.5%)

(Subject D Y, Table VIII) The titers developed by the next group (Group 2) were lower and ranged from 1:20 to 1:160. In Group 3, the single elevation which occurred was to 1:40.

The sera of the sixteen subjects in whom agglutinins for *Brucella* had appeared were also tested for opsonins before and after the ingestion of *Brucella*. In seven of these there were increases ranging from 10 to 90 over the initial phagocytic index (Table VIII).

Finally, the ability of dead *Brucella* to sensitize the skin was investigated in eighteen persons who ingested 100 million organisms daily for ten to twenty feedings. Sixteen of the eighteen had negative skin tests with *Brucelle*igen antigen after the feedings were discontinued. Two persons having positive tests at the beginning of the experiment showed no alteration in skin sensitivity as a result of the feedings.

#### DISCUSSION

These results demonstrate that the ingestion of nonviable *Brucella* may give rise to the production of agglutinins or opsonins. This may help explain the occurrence of agglutinins in the blood of some asymptomatic persons who inhabit areas where Bang's disease is prevalent in cattle. Under naturally occurring circumstances, dead *Brucella* may be ingested in pasteurized milk or may result from the action of gastric juice on living organisms which enter the stomach in raw milk. Studies now in progress in this laboratory have demonstrated a definite bactericidal action of human gastric juice against *Brucella*.

This study also suggests that the development of dermal hypersensitivity does not accompany the production of agglutinins after the ingestion of dead *Brucella*. Most individuals whose sera contain *Brucella* agglutinins also display dermal hypersensitivity to *Brucella* antigens. In the survey made by Aagaard,<sup>6</sup> the incidence of negative intradermal reactions was only 4 per cent in such persons. In a group of sixty-five subjects giving positive agglutination tests, Braude<sup>2</sup> found only four (6 per cent) who did not react to any one of four *Brucella* antigens applied intradermally. Persons who might acquire agglutinins in their sera by the ingestion of pasteurized milk containing large numbers of heat-killed *Brucella* would, therefore, be expected to comprise a relatively small percentage of all those having positive agglutination tests.

Several factors may account for the negative intradermal reactions which were observed in subjects who were examined for hypersensitivity after ingesting heat-killed *Brucella*. The quantity of *Brucelle*igen employed in each test was the usual dose of 0.1 milligram. This amount may be inadequate for eliciting positive reactions in the presence of a small degree of hypersensitivity. Exposure of the organism to both heat and gastric juice may remove the antigenic components which are responsible for inducing hypersensitivity. It has been reported that dead *Brucella* may induce hypersensitivity when injected into the tissues of experimental animals. Leon and Sosa<sup>11</sup> observed that positive intradermal reactions to *Brucella* antigens were obtained in rabbits after the repeated injection of dead *Brucella*. Similar results have been noted in this laboratory in studies made in guinea pigs, although the reactions were of much weaker

intensity than those occurring in animals infected with *Br. abortus*. On the other hand, Fleischner and Meyer<sup>1</sup> were able to stimulate the production of agglutinins in the sera of guinea pigs but could not sensitize their skins by the repeated injection of millions of heat killed *Brucella*. Stroem<sup>12</sup> failed to produce sensitivity in guinea pigs when heat killed *Brucella* were introduced with an adjuvant (Kieslgut). These discrepancies in the reports of various authors may be the result of differences in the strains and quantities of *Brucella* which were used in the respective experiments. In the present investigation, observations were limited to the effects of only one strain. It will be necessary to repeat these studies in human subjects with a number of strains administered over a longer period of time.

It is presumed that the production of agglutinins in this study was related to the passage of *Brucella* antigen from the intestine into the blood. Such an absorption of undigested antigens by the intestinal mucosa has been demonstrated by several investigators. By means of the Prausnitz-Kustner reaction the absorption of undigested fish and egg proteins in human beings has been noted by Walzer<sup>14</sup> and Ratner and Gruhl.<sup>8</sup> They have also shown that guinea pigs may be sensitized and later killed by anaphylactic shock if they are fed cows' milk on successive occasions. Hektoen<sup>1</sup> using the precipitin test, detected the presence of thyroglobulin in the portal blood of dogs which were fed beef thyroid. The results which we obtained by feeding dead *Brucella* organisms may be regarded as additional evidence of the permeability of the intestinal mucosa to proteins. There is also a possibility that the whole *Brucella* cell can permeate the intact mucosa. Arnold<sup>15</sup> has found that typhoid and coliform bacilli entered the thoracic duct and reached the liver in large numbers after these bacilli were placed in the duodenum of dogs.

It is difficult to explain why agglutinins failed to appear in the sera of guinea pigs after they were fed massive doses of heat killed *Brucella*. One of us (A. B.) has observed in other experiments that agglutinins can be produced in guinea pigs by the injection of heat killed *Br. abortus* into their skins. The titers which were produced in the sera of these animals were somewhat less than might be expected. Animals which were injected with a total of one billion to ten billion organisms over a period of eight to twelve weeks developed agglutinin titers in their sera which seldom exceeded 1:160 and often measured only 1:40 or 1:80. It appears therefore that agglutinins may not be produced readily in guinea pigs by the administration of dead *Brucella* and that oral doses even more massive than we employed may be necessary for the production of agglutinins in these animals.

#### SUMMARY

1. Heat killed *Brucella* cells were suspended in water or in milk and fed to sixty-seven human volunteers. In sixteen, or 23.9 per cent of the individuals, agglutinins appeared in the sera after the period of feeding.

2. Dermal hypersensitivity to *Brucella* antigen was not induced by the ingestion of nonviable *Brucella*.

## LABORATORY AND CLINICAL OBSERVATIONS ON AEROSPORIN (POLYMYXIN B)

ERNEST JAWETZ, M D, PH D, AND VIRGINIA R. COLFMAN, A B  
SAN FRANCISCO, CALIF

**A**N ANTIBIOTIC substance with remarkable activity against gram negative bacteria was reported recently by Brownlee and Bushby.<sup>1</sup> This substance, Aerosporin (Polymyxin A) is a polypeptide produced by the soil organism *Bacillus aerospirius* Green. The bacillus was found to be identical with *Bacillus polymyxa* (Prazmowski) Migula<sup>2</sup> from which Stansky and co-workers<sup>4</sup> had derived another antibiotic substance Polymyxin (Polymyxin D). Further study indicated<sup>3</sup> that *B. polymyxa* produced a number of peptides with similar antibiotic properties but differing from each other in their amino acid content and then toxicity for animals.

One of the polypeptides (Polymyxin D), extensively investigated in the laboratory by Stansky and associates<sup>4,5</sup> was given an early clinical trial by the group at the Johns Hopkins Hospital.<sup>9,11</sup> Polymyxin D was very active against many gram negative bacteria both in vitro and in animals, its toxicity for animals was relatively low and it appeared to be clinically useful. However, definite evidence of renal toxicity was soon discovered and clinical use of the drug was abandoned.<sup>12</sup>

Another peptide produced by *B. polymyxa*, Aerosporin (Polymyxin A) was shown to be five to fifty times more active by weight against certain gram negative bacteria than streptomycin.<sup>1</sup> Its antibacterial spectrum resembled that of Polymyxin D. It was claimed to be bactericidal rather than bacteriostatic and susceptible organisms did not readily develop resistance to its action. It did not contain the amino acid, *D* serine believed to be nephrotoxic. Clinical trials<sup>13</sup> of Polymyxin A indicated good response in children with whooping cough and in other infections with gram negative bacteria.

These reports suggested a trial of this group of drugs in infection of the urinary tract caused by gram negative organisms in which the effect of the antibiotic could be studied quantitatively by bacteriologic methods. Observations made in the laboratory and on patients in the course of these trials are reported here.

### MATERIALS AND METHODS

The drug preparation used was Aerosporin Brand Polymyxin B (Hydrochloride) ND No 110,\* hereafter referred to as Polymyxin B. It was supplied

From the Departments of Bacteriology and Pediatrics, University of California Medical School.

Supported in part by a grant from the Research Committee of the University of California Medical School.

Received for publication March 11 1949.

Kindly supplied in generous amounts by Dr D S Searle Burroughs Wellcome & Co Inc. Tuckahoe 7 N Y.

in vials each of which contained 60 mg of white amorphous material equivalent to 40 mg of Polymyxin B. Solutions of desired strength were prepared by dissolving the contents of a vial in unbuffered 0.85 per cent sodium chloride solution. At the beginning of this investigation a random sample of Polymyxin B was diluted to a concentration of 200  $\mu$ g per milliliter, frozen, and stored in ampules at  $-70^{\circ}\text{C}$ . This sample was used as standard of reference in all laboratory tests.

Bacteria isolated from the urine of patients with infection of the urinary tract were grown in Proteose-peptone broth (Difco) for eighteen hours at  $37^{\circ}\text{C}$  and the density of the culture was then adjusted with broth to that of the McFarland tube No. 2. For the determination of bacterial sensitivity, 0.2 ml of a  $10^{-4}$  dilution of such a culture was used in a tube dilution procedure slightly modified from Brownlee and Bushby<sup>1,5</sup>. The tubes were uniformly incubated at  $37^{\circ}\text{C}$  and read after eighteen hours. A standard organism (*Escherichia coli*) of known and constant susceptibility to Polymyxin B was included in each test.

Serum levels of Polymyxin B were estimated by a method<sup>5</sup> similar to that used for determination of penicillin in blood serum<sup>14</sup>. The frozen stock of Polymyxin B served as standard of reference.

#### EXPERIMENTAL

*1 Physical Characteristics of the Drug*—The contents of vials dissolved rapidly and completely in water or physiologic salt solution, forming a clear, colorless solution of pH 7.2 to 7.4. Sixty milligrams dissolved readily in 2 ml of solvent. The stability of such solutions was remarkable. At  $-70^{\circ}\text{C}$ , in solutions containing 200  $\mu$ g per milliliter, there was no loss of activity over a period of five months. Activity was evaluated both against organisms of known and stable sensitivity and against freshly prepared solutions. Although very dilute solutions deteriorated slowly at room temperature, in concentrations of 4 mg of Polymyxin B per milliliter antibacterial activity was not significantly diminished after sixty-two days at either  $4^{\circ}\text{C}$  or  $37^{\circ}\text{C}$ . The dry preparation was stable for at least five months at  $22^{\circ}\text{C}$ .

Changes in hydrogen ion concentration did not greatly influence the antibacterial effect of the drug. Polymyxin B had the same effect on the standard strain of *Esch. coli* when tested in buffered broth at pH 4.2, 5.0, 7.0, or 7.4 and was only slightly less inhibitory at pH 9.2.

*2 Sensitivity to Polymyxin B of Bacteria Isolated From the Urine*—Strains of bacteria freshly isolated from the urine of patients were examined for their sensitivity to Polymyxin B in vitro. Table I indicates the range of organisms isolated and their relative sensitivities. The activity of Polymyxin B against bacteria encountered frequently in urinary tract infections agrees well with that observed for Polymyxin D<sup>7</sup>. Early clinical experience indicated that organisms with a sensitivity of 1.0  $\mu$ g per milliliter or more in vitro uniformly failed to respond to therapy with Polymyxin B. Determinations of sensitivity were consequently limited to a range 0.04 to 1  $\mu$ g per milliliter.

TABLE I IN VITRO SENSITIVITY TO POLYMYXIN B OF BACTERIA ISOLATED FROM URINARY TRACT INFECTIONS

BACTERIAL SPECIES	NUMBER OF STRAINS	NUMBER NOT IN HIBITED BY $\mu\text{G}/\text{ML}$	NUMBER OF STRAINS INHIBITED BY POLYMYXIN B				
			$\mu\text{G}/\text{ML}$				
			1	0.4	0.2	0.1	0.05
<i>Escherichia coli</i>	22	0	0	2	15	4	1
<i>Aerobacter aerogenes</i>	16	0	6	8	2	0	0
<i>Pseudomonas aeruginosa</i>	18	4	5	8	1	0	0
<i>Proteus vulgaris</i>	5	3	2	0	0	0	0
<i>Streptococcus faecalis</i>	7	7	0	0	0	0	0
<i>Shigella</i> sp	4	2	1	0	1	0	0
<i>Salmonella</i> sp	4	0	0	2	1	1	0
<i>Paracolon bacilli</i>	2	0	0	0	2	0	0

All strains of *Esch coli*, *Salmonella* and *paracolon bacilli* which were examined were inhibited by  $0.4 \mu\text{g}$  per milliliter or less. *Aerobacter aerogenes* strains tended to be less susceptible, and *Proteus vulgaris* and *Pseudomonas aeruginosa* were still more resistant. This scale of susceptibility resembles that commonly experienced with streptomycin and ampicillin.<sup>15</sup>

The action of Polymyxin B appeared to be bactericidal rather than bacteriostatic. The end point in a tube dilution series was usually not changed when the test was incubated for seven days at  $37^{\circ}\text{C}$  after the first observation. There was no growth in subcultures made on solid or in liquid media from the last tube in which no growth occurred. The growth of resistant strains in the presence of Polymyxin B did not destroy it. These organisms, grown in broth containing the drug were centrifuged out and the supernatant fluid was tested for antibiotic activity with the standard strain of *Esch coli*. Its activity was unchanged.

3 *Bacterial Resistance to Polymyxin B*—An effort was made to induce resistance to Polymyxin B in vitro with four susceptible bacterial strains. Daily transfers were made in broth containing increasing amounts of the antibiotic. The increase in resistance in these four random gram negative organisms is shown in Fig 1. The strain of *A. aerogenes* was originally inhibited by  $0.2 \mu\text{g}$  per milliliter and after a regular step wise increase in resistance in the course of thirteen transfers it grew freely in  $1,000 \mu\text{g}$  per milliliter. A strain of *Ps. aeruginosa* showed a similar but less regular change in susceptibility. One strain each of *Esch coli* and *Salmonella choleraesuis* changed but little in two weeks of daily transfers in broth containing Polymyxin B. Not only did these organisms fail to increase in resistance but also repeatedly, no growth was obtained when subcultures were made from tubes in which there was visible turbidity perhaps indicating that the drug was slowly killing the organism.

Strains that acquired resistance to Polymyxin B kept this characteristic when subcultured daily for fourteen days in plain broth. No bacteria dependent on Aerosporin (Polymyxin B) for growth have been observed to date.

The occurrence of naturally resistant individuals in bacterial populations was tested by means of massive inocula on solid media. When Polymyxin B was added to Proteose peptone agar (Difco), tests made with small inocula of bacteria indicated sensitivities comparable with those found by the tube

TABLE IV TREATMENT OF A PATIENT WITH URINARY TRACT INFECTION WITH POLYMYXIN B  
RELATION OF DRUG TO CLINICAL AND LABORATORY FINDINGS  
(A 73 YEAR OLD MAN WHO HAD A NEPHRECTOMY TEN YEARS BEFORE, NOW HAS PYELONEPHRITIS  
[CHRONIC] IN THE REMAINING KIDNEY)

DAY	1	2	3	4	5	6	7	13	27
Polymyxin B	0	120	80	120	80	0	0	0	0
Dose (mg/day)									
Average serum levels ( $\mu\text{g/ml}$ )	0	1.3	2.5	4.10	4.10	1.4	0	0	-
Toxic symptoms									
Paresthesias	0	+	++	+	+	-	-	-	-
"Dizziness"	0	-	+	+	+++	+	-	-	-
Ataxia	0	-	-	+	-	-	-	-	-
Blood examinations									
Hemoglobin (Gm %)	15.0					15.3			14.8
White blood cells/ $\text{c mm}$	6,000					8,750			9,500
Polymorphonuclears (%)	65					69			71
Eosinophiles (%)	1					4			2
Blood urea (mg %)	72					51			59
Urea nitrogen (mg %)	34					21			24
Urine examinations									
White cells/high dry field	++++	+++	+++	++	5-10	2-3	2-3	2-3	++
Red cells/high dry field	+	+	+	Rare	Rare	0	0	0	Occasional
Bacteria/high dry field	++++	+++	++	+	Rare	Rare	0	0	+++
Protein (mg %)	52	21			63		25		44
Urine culture (Bacteria/ ml)									
Esch coli	80,000		1,000		0	0	0	0	20,000
Proteus sp	1,000		100		10		10	50	500

they were resumed. No effect was observed on the red or white cell count in the ten patients.

The most marked undesirable effect of Polymyxin B was on the central nervous system. Within forty-eight hours of inception of treatment, the majority of patients experienced circumoral paresthesias and "dizziness" without nausea, anorexia, or true vertigo. There was commonly mild ataxia and occasionally the feeling of weakness of the legs without objective evidence of diminished muscular strength. These symptoms lasted while the drug was administered and subsided in all patients in thirty-six to forty-eight hours after it was discontinued. No residual disturbances were observed in any patient.

With doses larger than those routinely used, more drastic effects on the central nervous system were observed. Two persons received 160 mg of Polymyxin B intramuscularly in twelve hours (i.e., 25 mg per kilogram per twelve hours). They experienced peripheral as well as circumoral paresthesias, severe incoordination, with dysarthria, dyssynergia, dysmetria, ataxia, a positive Romberg sign and marked past pointing. The reflexes were within physiologic limits. There was no true vertigo, only "lightheadedness," no tinnitus or impaired hearing, and the appetite was unimpaired. These symptoms and signs persisted for thirty-six hours while the serum concentration of the drug was in excess of 10  $\mu\text{g}$  per milliliter, they then gradually subsided and left no sequelae.

An effort also was made to find out whether exposure of bacterial populations to Polymyxin B for three to five days *in vivo* might induce resistance. In a number of patients the sensitivity of strains recovered prior to treatment could be compared with that of similar organisms cultured from the urine after therapy. No increase in resistance was observed, regardless either of the clinical course or of the response to the drug.

## SERUM LEVELS OF POLYMYXIN B

Fig. 2

*4 Serum Levels of Polymyxin B in Patients With Urinary Tract Infection*—For intramuscular administration, solutions of Polymyxin B were prepared by adding 2 ml of saline and 1 ml of procaine, 1 per cent, to the dry amorphous material equivalent to 40 mg of pure drug. Without the local anesthetic the injection was painful and tenderness persisted for some hours. Ordinarily 20 mg of drug were injected in a volume of 1.5 ml for each dose. In a few instances 10 mg were administered for from one to four doses. Injections were given every four to eight hours.

Early observations indicated accumulation of the drug, administered with procaine every four to eight hours. Consequently levels in serum were estimated usually after multiple doses. Fig. 2 shows the levels in four patients in whom there was no evidence of nitrogen retention from one to six hours after the fourth dose of 20 mg Polymyxin B administered every four hours. In individuals with impaired renal function and retention of nitrogenous waste products there was an increased accumulation of the drug (Fig. 2). In such patients serum levels of 2 to 5 µg per milliliter usually could be maintained by the injection of 20 mg Polymyxin B every eight hours, and measurable levels of the drug could be detected eighteen to twenty-four hours after the last of eight to twelve injections.

In two patients, four hours after a single injection of 40 mg, the serum concentration of Polymyxin B was 13 to 20  $\mu\text{g}$  per milliliter. After four such injections (with procaine), the serum levels were, respectively, 30 and 20  $\mu\text{g}$  at two hours, 5 and 8  $\mu\text{g}$  at seven hours, and 3 and 6  $\mu\text{g}$  at twelve hours after the fourth injection. There were toxic symptoms in both patients during this period.

Measurement of the drug in the urine was not satisfactory. Filtration through Sartz pads removed a considerable portion of Polymyxin B, and in boiled urine the drug levels were very irregular.
